The entire organization of operons on the *Bacillus subtilis* genome

Hirokazu Kobayashi

Abstract

In the post-genomic era, comprehension of cellular processes and systems requires global and non-targeted approaches to handle vast amounts of biological information. The present study predicts transcription units (TUs) in *Bacillus subtilis*, based on an integration of *B. subtilis* experimental data involving DNA sequence and transcriptome analyses. First, co-expressed gene clusters are predicted by calculating the Pearson correlation coefficients of adjacent genes for all the genes in a series that are transcribed in the same direction with no intervening gene transcribed in the opposite direction. Transcription factor (TF) binding sites are then predicted by detecting statistically significant TF binding sequences on the genome using a position weight matrix. This matrix is a convenient way to identify sites that are more highly conserved than others in the entire genome because any sequence that differs from a consensus sequence has a lower score. I identify genes regulated by each of the TFs by comparing gene expression between wild-type and TF mutants using a one-sided test. By applying the integrated approach to 11 σ factors and 17 TFs of *B. subtilis*, I am able to identify fewer candidates for genes regulated by the TFs than were identified using any single approach, and also detect the known TUs efficiently. Using these TU data, I predicted the genome-wide operon structure in the *B. subtilis* genome by comparative genomic analysis of 55 gram positive bacteria. This integrated approach showed determining to appropriate boundaries of operons efficiently and I identified some internal operons. Furthermore, I took another operon prediction approach by a support vector machine (SVM)-based classification algorithm. SVM is one of the supervised machine learning methods. I used five types of features: intergenic distances, expression profiles, two comparative genomic data and gene functional data, and separated all consecutive gene pairs into operon pairs and boundary pairs on a 10-dimensional feature hyperplane and efficiently identified operon structures. Finally I combined the results of these approaches, and demonstrated new operon structures in the *B. subtilis* genome

Keywords: operon, microarray, position weight matrix, *Bacillus subtilis*, false discovery rate, comparative genomics, support vector machine

1 Preface

The first discovered operon was the lactose operon in *Escherichia coli*, which consists of three genes, *lacZ*, *lacY* and *lacA* [Jacob and Monod 1961]. These three adjacent genes are required for the transport of lactose and expressions of these genes are induced in response to abundance/scarcity of lactose in *E. coli* and some other bacteria. The *lac* operon is regulated by several factors, one of which is the availability of lactose as an energy source. Control of the *lac* genes was the first elucidation of the genetic regulatory mechanism controlled by the *lac* repressor and positive regulatory elements. The *lac* repressor is made up of four identical polypeptides, homotetramer. Part of the molecule has sites that enable it to recognize and bind to the 24 base pairs of the *lac* operator. Another part of the repressor contains sites that bind to lactose. When lactose unites with the repressor, it causes a change in the shape of the molecule, so that it can no longer remain attached to the DNA sequence of the operator and prevents transcription. On binding of lactose to the repressor, the *lac* repressor leaves the operator, and three genes are expressed together. The genes of the operon are *lacY* coding for the lactose permease that transports lactose into the cell, *lacZ* coding an intracellular enzyme, β-galactosidase that cleaves the disaccharide lactose into glucose and galactose, and *lacY* coding a transport protein, β-galactoside permease that pumps lactose into the cell. Specific control of the *lac* genes depends on the presence of the substrate lactose in the growth medium. These genes are organized into an operon such that they are oriented in the same direction immediately adjacent on the chromosome and are co-transcribed into a single mRNA molecule, and the mRNA is then translated into protein, only when lactose is present. This elucidation of the control of expression of genes in the *lac* operon brought the Nobel Prize in Physiology or Medicine for Jacques Monod and Francois Jacob in 1965.

Mechanisms of gene transcription in the upstream of protein coding regions by gene regulatory proteins are summarized in Figure 1. An operon is one or more structural genes, and all the genes in an operon are expressed as a single unit and are transcribed into one mRNA. In the present study, a set of genes transcribed into an identical mRNA is referred to as a **transcription unit** (**TU**) or an **operon**. At the upstream of the operon, there are an operator and a promoter that are gene expression regulation sites. An operator is a segment of DNA that regulates the activity of the transcription by interacting with a specific gene regulatory protein and exits in both the upstream and downstream of the promoter. For example, the lambda repressor and *lac* repressor bind upstream and downstream of promoters respectively and inactivate particular transcriptions

[Pabo and Sauer 1984; Matthews and Nichols 1998]. In negative control of an operon, a repressor protein binds to the operator and prevents transcription of the genes composing the operon. Most repressor proteins are produced by regulator genes but they are unable to bind to the operators in their normal conformation. When a ligand binds to (Fig. 1A1) or is released from the repressor protein (Fig. 1A2), the conformation of the repressor protein changes and the repressor protein can bind to the operator. The activated repressor protein binds to the operator and prevents transcription (Fig. 1A). When the repressor protein is unbound from the operator by the presence or removal of inducer molecules, its conformation changes and the transcription of the genes begin in reverse. Operons can also be positively controlled (Fig. 1B). When ligands bind to (Fig. 1B1) or are released from the activator protein (Fig. 1B2), the conformation of activator protein changes and the protein binds to the operator, and then the activator stimulates transcription by binding the RNA polymerase holoenzyme, and operates it. In this study, I regarded these proteins, repressor and activator, to be **transcription factors** (**TFs**). A promoter site is recognized by RNA polymerase which then binds and initiates transcription. In the process, the RNA polymerase core enzyme reads the signal of transcription beginning in the DNA with the assistance of detachable subunits called σ-factors. Therefore, transcription of the genes is promoted with the presence of σ-factors.

After determining complete the *Bacillus subtilis* genome sequence [Kunst et al. 1997], characterization of operons provides the basic knowledge to understand the gene organization of genomes and regulatory networks. The organization of operons is considered to facilitate the efficient coordinated regulation and association of functionally related protein products. A number of bioinformatic approaches have been carried out for operon prediction. The purpose of this thesis is to clarify organization of TUs and gene-regulated relations in the whole genome of *B. subtilis* based on an integrated approach consisting of genome sequences and transcriptome analyses. In chapter 2, I review the current progress of operon prediction techniques in bioinformatics. In the *B. subtilis* genome, about 300 operons consisting of approximately 1,000 genes have been experimentally determined and 18 σ-factors and 384 TFs are predicted by computational analyses [DBTBS]. Among the genes that encode the TFs, there exist 270 genes concerning transcription regulation in the *B. subtilis* genome, consisting of 18 σ-factors, 201 TFs with the Helix-Turn-Helix motif, 35 TFs with a two-component system, 16 RNA-binding-regulators, and 16 other factors including anti-terminators. The final goal of the

gene regulation networks in *B. subtilis* is to clarify relations between transcription regulation between those and targeted genes, and to understand whole gene expression regulation systems. To attain this purpose, I examine a gene regulation network using σ-factors and TFs whose DNA-binding sites in transcription regulation are determined. In chapter 3, I discuss an approach for prediction of TUs based on the integrated approach for TU prediction and general properties for TUs in the *B. subtilis* genome, and examine conservation of TUs in the *B. subtilis* genome in comparison to the order of genes in 55 Gram-positive bacteria and predict the genome-wide operon structure in the *B. subtilis* genome by comparative genomic analysis of 55 Gram-positive bacteria. In chapter 4, I apply support vector machine (SVM) to predict operons using a large amount of microarray data published by NCBI and operon compositions in the *B. subtilis* genome. Chapter 4 also contains the discussion on advantages and disadvantages between the integrated and the SVM approaches. Finally, in chapter 5, I summarize the perspective of bioinformatics focused on operon prediction based on the whole regulation networks of *B. subtilis* genes.

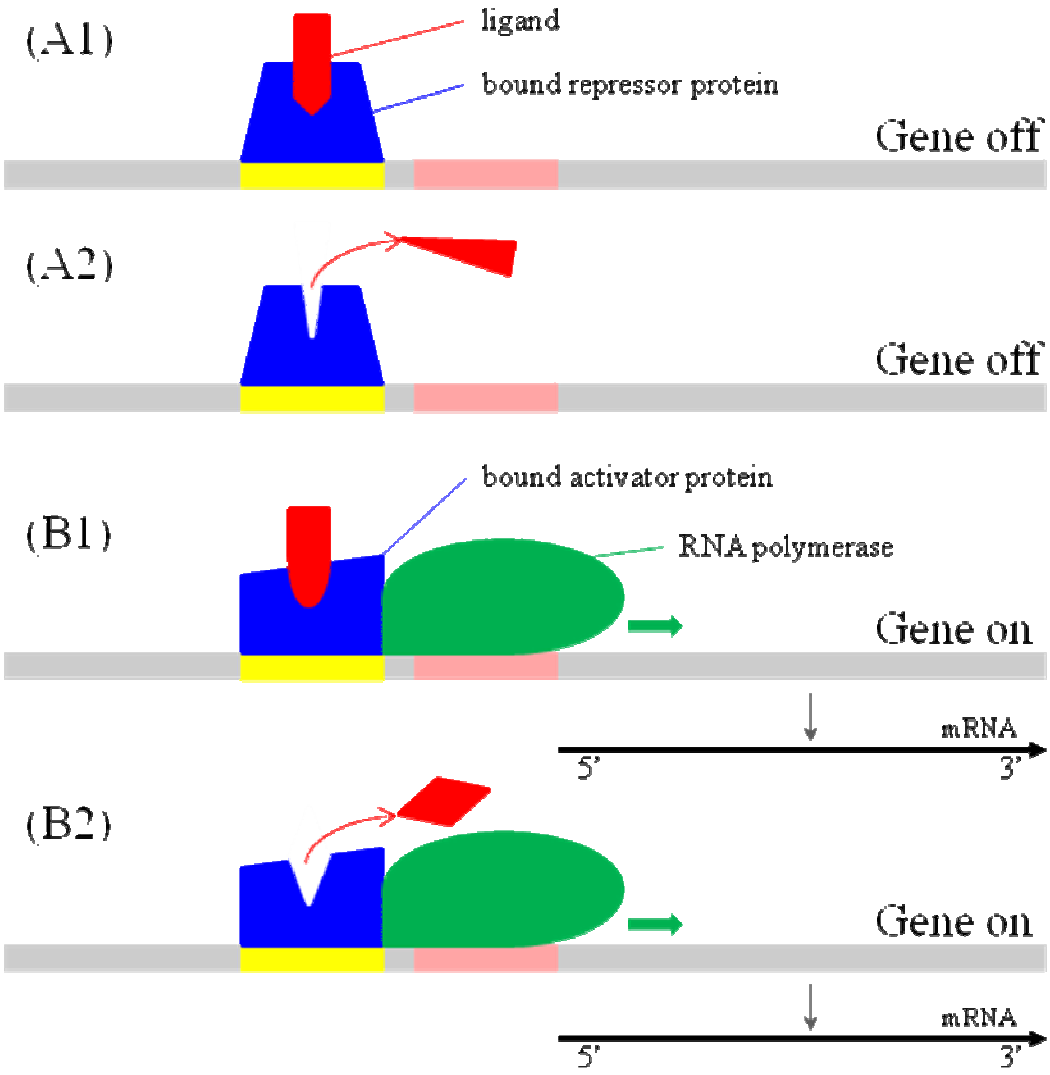

Figure 1. Mechanisms of gene transcription in upstream of protein coding regions by gene regulatory proteins. (A) Negative regulation of gene transcription by repressor protein binding to DNA (A1) with addition of ligand, and (A2) with removal of ligand. (B) Positive regulation of gene transcription by activator protein binding to DNA (B1) with addition of ligand, and (B2) with removal of ligand.

2 Bioinformatic approaches for operon prediction

A number of bioinformatic approaches have been carried out for operon prediction from genome sequences, high-throughput expression profile experiments such as cDNA microarray and GeneChip. Bioinformatic approaches for operon prediction can be classified into five categories, (i) intergenic distance between genes and (ii) detecting transcription control signals, that is, existence of promoters and terminators, (iii) the conservation of operon structures based on comparative genomics, (iv) co-expression relations and (v) integrated approaches.

2.1 Intergenic distances

Statistical analysis of experimentally determined operons has established that genes within an operon tend to have much shorter intergenic distances than those at the borders of the operon. A log-likelihood function of intergenic distance for predicting operons was developed in comparison of intergenic distances within-operon and between-operon gene pairs for the *Escherichia coli* genome, and identified well the known *E. coli* operon [Salgado et al. 2000]. This method has used for the most generally applicable and successful pairwise operon prediction method in many prokaryote genomes.

2.2 Detection of transcription control signals

Existence of promoters and terminators is a clue for operon prediction. Operon prediction has been carried out by distinguishing co-directional TU boundaries from intergenic TU boundaries in operons by densities of signa-70 promoter like signals because of the trend that in *E. coli,* regions upstream of TU contain higher densities of sigma-70 promoter-like signals than both coding regions and the intergenic region downstream of the convergent transcribed genes [Huerta and Collado-Vides 2003; Janga et al. 2006]. The recognition rates of the two types of experimentally determined boundaries using the densities of tri-nucleotide signatures are 78% for *E. coli*, and 72% for *B. subtilis*. Construction of a Hidden Markov Model (HMM) based on known promoters and terminators in *E. coli* makes it possible to predict 60% of known operons [Yada et al. 1999]. Nucleotide sequence patterns at the initiation and termination sites of transcription conserved across multiple genomes makes it possible to predict operons but these sequence motifs are short and can be highly variable, limiting the prediction capability of this method [Thieffry et al.1998].

2.3 Conservation of operon structure based on comparative genomics

There has been a variety of operon prediction methods, including those that use comparative genomic strategies. These methods utilized nucleotide or peptide sequences [Wang et al. 2004; Edwards et al. 2005]. If I use such a method alone, the data it depends on are only available for a selected subset of bacterial species, so that it is difficult to detect the independent results of query genome data. Functions of genes are conserved across related genomes [Overbeek et al. 1999]. Many sets of genes occur in conserved orders on multiple genomes across long stretches of evolutionary time, representing candidate operons. A comparative genome analysis on 34 prokaryotic species led to the conclusion that more than 7600 pairs of genes are highly likely to belong to the same operon [Ermolaeva et al. 2001]. Through taking a certain distance between adjacent genes into consideration, this method allows highly confident prediction of operons in a wide variety of species but using this method, a large portion of the known operon in *E. coli* cannot be predicted. The fairly low sensitivity of this method is due to the low conservation at the operon level between phylogenetically distant genomes [Wolf et al. 2001].

2.4 Function similarity of genes in operons

Genes in an operon tend to encode enzymes that catalyze successive reactions in metabolic pathways. This concept was applied, using 42 prokaryotic species, to predict operons [Zheng et al. 2002]. This method is useful for the purpose of estimating putative operon structures, but cannot predict operons that include unknown function genes.

2.5 Co-expression relations

When microarray gene expression data has become available, the accuracy of operon prediction has been greatly elevated. Sabatti et al. [2002] compiled data from 72 cDNA microarray experiments for *E. coli* and predicted operons based on a Bayesian classification using the correlation between expression ratios of adjacent genes. This method allows a significant refinement of the sequenced-based predictions described above. Yamanishi et al. [2003] applied a generalized kernel canonical correlation analysis to group genes, which share similarities with respect to position within genome and gene expression. However, this method was restricted to a subset of *E. coli* genes that comprised known metabolic pathways.

2.6 Integrated approaches for operon prediction

The prediction rate of operons using both DNA sequence and microarray expression data has been better than those performed using only one type of data. For example, Bockhorst et al. [2003] presented a probabilistic machine-learning approach to predicting operons based on Bayesian networks using diverse evidence sources including gene coordinate, operon length, promoter and terminator signal, codon usage frequency and cDNA microarray expression data. Expression profiles of genes are dynamic; on the other hand, genome information including gene organization, and intergenic DNA sequences is static. Multi-factorial data such as transcriptome and genome information should be combined for predicting operons and thus development of element technology in bioinformatics toward combining the multi-factorial data has been needed for operon prediction. Previous studies have demonstrated that multiple factors of information including intergenic distances [Salgado et al. 2000], transcription control signals [Huerta and Collado-Vides 2003], conservation of operon structure [Ermolaeva et al. 2001], function similarity of genes [Zheng et al. 2002] and co-expression gene relations [Sabatti et al. 2002] are effectively utilized for predicting operon structures in genomes. Integration of these multiple factors could lead to predicting operon structures effectively, and the way to do so is an important subject in this study. Consequently, in the present study, we try to develop a method for identifying operons in *B. subtilis* by integration of these factors.

3 The integrated approach to identification of operons

3.1 Transcription unit prediction by integration of *B. subtilis* data

3.1.1 Introduction

Recent progress in genome projects has generated a vast amount of nucleotide sequence data, and analyses of gene expression by global approaches have started to broaden understanding of cell systems. As a useful model for systems biology and genomics, many studies use *B. subtilis*, a spore-forming Gram-positive bacterium whose genome sequence has been determined [Kunst et al. 1997]. The ultimate goal of post-genome analysis is to specify transcriptional regulation in the entire genome. Computational algorithms to locate TUs have been developed based on analysis of signal sequences that are located at the boundaries of TUs from promoters to terminators, homologous gene pairs on other genomes, intergenic distance, functional categories, and gene clusters conserved among various species [Ermolaeva et al. 2001; Huerta et al. 1998; Salgado et al. 2000; Wang et al. 2004; Westover et al. 2005; Yada et al. 1999]. In the present study, a string of one or more genes co-transcribed is defined as a TU [Salgado et al. 2000].

Identification of σ-factors and TFs and their binding sites on their target genes is an important element of transcriptome analysis in the post-genome-sequencing era. Various approaches have been taken to identify specific DNA-binding sites of σ-factors and TFs. DNA-binding specificities have traditionally been determined by experimental techniques such as DNase I footprinting and electromobility shift assay [Ogasawara et al. 1985; Schujman et al. 2003]. More recently, the binding sites have been predicted by computational techniques such as hidden Markov models (HMMs) [Moreno-Campuzano et al. 2006] and position-weight matrices (PWMs) [Stormo 2000; Qiu et al. 2003]. The PWM has one column for each position in the binding site and one row for each nucleotide. Each of the matrix elements is proportional to the relative frequency of the corresponding nucleotide at each position, and the score for a particular site is the sum of the matrix values for the sequence. Therefore, PWM is often used to predict nucleotide-protein binding sites and is used in the TRANSFAC database, which covers many known TFs and binding sites [Heinemeyer et al. 1998]. This approach is a convenient way to identify positions that are more highly conserved than others in a whole genome, because any sequence that differs from a consensus sequence has a lower score. The accuracy of detecting promoter sequences thus

depends on the conservation of these binding sites.

I can now use complete genomic DNA sequences from several species and analyze massive amount of data on differential gene expression in microarray experiments [Kobayashi et al. 2001]. Using microarrays in various conditions, I can obtain co-expression patterns for adjacent genes, which is an important property for determining TUs.

In the present chapter, I identify the TUs in *B. subtilis* using a combination of (i) a bioinformatics approach, using PWM methods that identify σ-factor and TF binding sites by detecting statistically significant binding sequences on the genome; and (ii) two DNA microarray analyses, one to predict co-expressed gene clusters by calculating Pearson correlation coefficients of expression profiles for neighboring genes, and the other to determine genes regulated by each of the TFs in the units by comparing gene expression between wild-type and TF deletion mutants in the genome.

3.1.2 Data

3.1.2.1 Microarray data

For prediction of co-expressed gene clusters, I used time-series gene expression data in *B. subtilis* 168. It was grown in 13 different time-series growth conditions: anaerobic growth; competent medium; cold-shock experiments; DSM medium; DGG medium; glucose-limited medium; heat-shock experiment; LB medium; minimum-glucose medium; sodium-shock conditions; phosphate-starvation medium; and SOS stress experiments.

Expression analysis of σ-factor and TF deletion mutants were applied to gene expression data from inactivate mutants of σ-factor and TF which were grown at 37^{o}C in different medium conditions: LB medium for *sigB, L, M, W, X, araR, ctsR, hrcA, iolR, lmrA, rocR, sinR, xylR* deletion mutants; LB medium with trace elements for *fur* and *perR* deletion mutants; DSM medium for *sigD, E, F, G, H, K, treR* deletion mutants; DSM medium with 2% Gln and 5% glucose for, respectively, *glnR* and *resD* deletion mutants; MC medium for the *comK* deletion mutant; MGM medium for the *ccpC* deletion mutant; and MGM with adenine and guanine for the *purR* deletion mutant.

3.1.2.2 Genomic data

The genome sequence of *B. subtilis* and the annotation files were obtained from National center for biotechnology (NCBI) ftp site [NCBI FTP]. The leading and lagging strands were scanned based on whether they were transcribed in the same directions or in different directions.

3.1.3 Methods

3.1.3.1 Methodology

Establishment of method to predict TUs in genome could aid in better understanding the role of unknown function genes. Then I made TU predictions by an integrated procedure (Fig. 2).

First, I selected directions [Edwards et al. 2005], series of genes transcribed in the same direction with no intervening genes in the opposite direction in the *B. subtilis* genome.

Second, co-expressed gene clusters were determined by correlating expression profiles between neighboring genes transcribed in the same directon (Fig. 2(1)). Co-expression between neighboring genes was estimated using a t-test of the Pearson correlation coefficient. To predict co-expressed gene clusters in the *B. subtilis* genome, I used 98 cDNA microarray data sets in 13 different time-series growth conditions.

Third, I regarded genes having promoters predicted by PWM as the start of the TUs (Fig. 2(2)). I examined the binding sequences of 11 σ factors and 17 TFs, which are known to possess multiple binding sites within 300 bp upstream of an open reading frame for all 4,225 genes of *B. subtilis* by PWM.

Fourth, I derived significant expression change data from σ-factor and TF deletion mutant microarray data to identify genes regulated by each of the σ-factors and TFs in the directon (Fig. 2(3)). In these analyses, I applied a one-sided test to examine genes whose expression changed significantly in the microarray data, and found candidates for the σ-factor and TF regulated genes.

Finally, the three approaches were integrated. I regarded σ-factor and TF regulative gene strings in co-expressed gene clusters beginning with detected promoters as TUs (Fig. 2(4)).

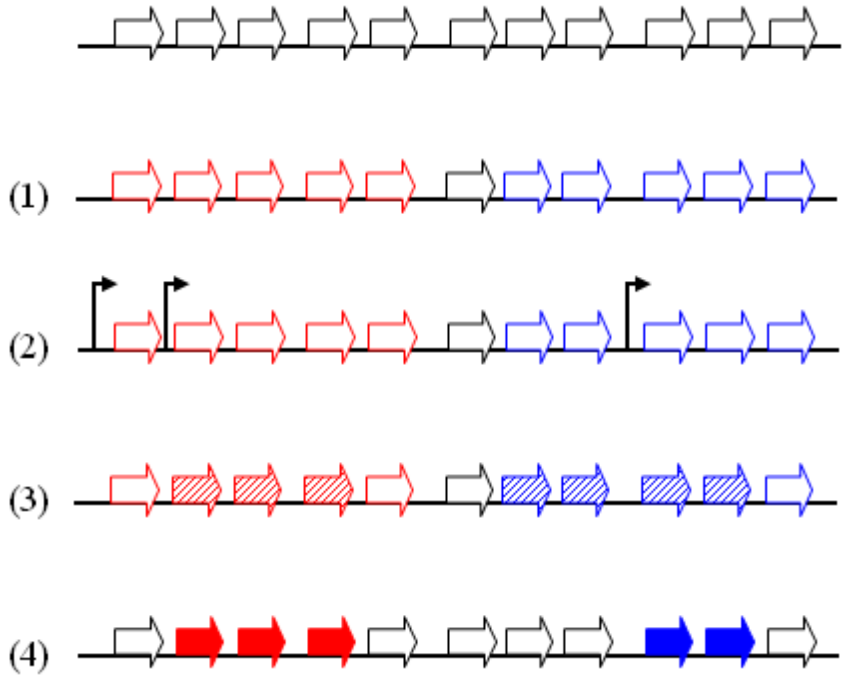

Figure 2. Outline of procedure for elucidating TUs by integrated analyses in gene organization on the genome. (1) Co-expressed gene clusters predicted by correlating expression profiles between neighboring genes; (2) σ-factor and TF binding site (thin arrows) prediction by PWM as the start of a TU in the putative co-expressed gene clusters; (3) detection of significantly expressed genes (stripe thick arrows) by comparison between σ-factor and TF deletion mutant arrays and wild ones; (4) identification of genes composing putative TUs (filled thick arrows) by integration of the three analyses.

3.1.3.2 Normalization in microarray experiments

Gene expression levels are evaluated by scanning the fluorescence intensity for each spot, and there is usually some experimental variation that occurs in every microarray experiment. It is, therefore, important to minimize experimental variation, and although several methods of microarray normalization have been developed [Quackenbush 2002; Yang et al. 2002], there are usually some false-positive data arising when analyzing gene expression data collected via microarrays.

Normalization of the logarithmic ratio of expression intensity between target (R_i) and control (G_i) experiments was carried out based on MA plots [Dudoit et al. 2002], which can show the intensity-dependent ratio of raw microarray data using TREBAX software [TREBAX]. The plots differed in the axes used. The MA plot used M_i ($\log_{10}(R_i/G_i)$) as the y-axis and A_i ($\log_{10}\sqrt{R_iG_i}$) as the x-axis. By plotting values of A_i on the abscissa and M_i on the ordinate of a coordinate system, it was possible to evaluate the bias error with respect to the average logarithmic intensities, and partial averages (PA_i) of the intensities were calculated on the assumption that the intensities of two experiments for most of genes was equivalent. PAv(s) was an average of logarithmic of expression intensities in *s*th width of 0.1 on the abscissa to obtain the following:

$$PAv(s) = \frac{\sum_{k=1}^{Ns} M_k}{\min(s)<Ai<\max(s)\ N_s}.$$

Here, min(s) and max(s) are minimum and maximum values of average logarithmic ratio of expression intensity between target and control experiments in the *s*th compartment, and Ns represents total number of the plots in the *s*th compartment. I then used the average, point by point, to correct the logarithmic ratio of expression intensity (M_i). The normalized log ratio M''_i was estimated as the difference between M_i and baseline M'_i as shown in Figure 3. Here, using the relation between M_i and A_i ($M_i = f(A_i) + \varepsilon_i$, where ε_i is the difference between M_i and $f(A_i)$ for *i*th gene for the MA plot), the baseline for the *i*th gene was estimated by $M'_I = f(A_i)$. Genes whose signal intensity for targeted or control experiments was regarded as zero were eliminated from the present analysis. With this methodology, it is assumed that there was no large error due to expression intensity in the majority of the spots.

The MA plots before and after the adjustments were shown in Figure 4. These plots before

the normalization tend to be dispersed especially in low intensity signal area (Fig. 4A). This is because stability of two types of fluorescent chemical marking cDNA: Cy3 and Cy5, differ according to the coloring effects respectively, and the effectiveness of the labelling process varies since the dyes embedment levels in cDNA differ and thus the image processing leads to a fluorescence intensity map containing two types of errors, i.e. random noise and bias. These plots after the normalization demonstrates that the bias error of the signal-specific to the florescence-material has been reduced (Fig. 4B).

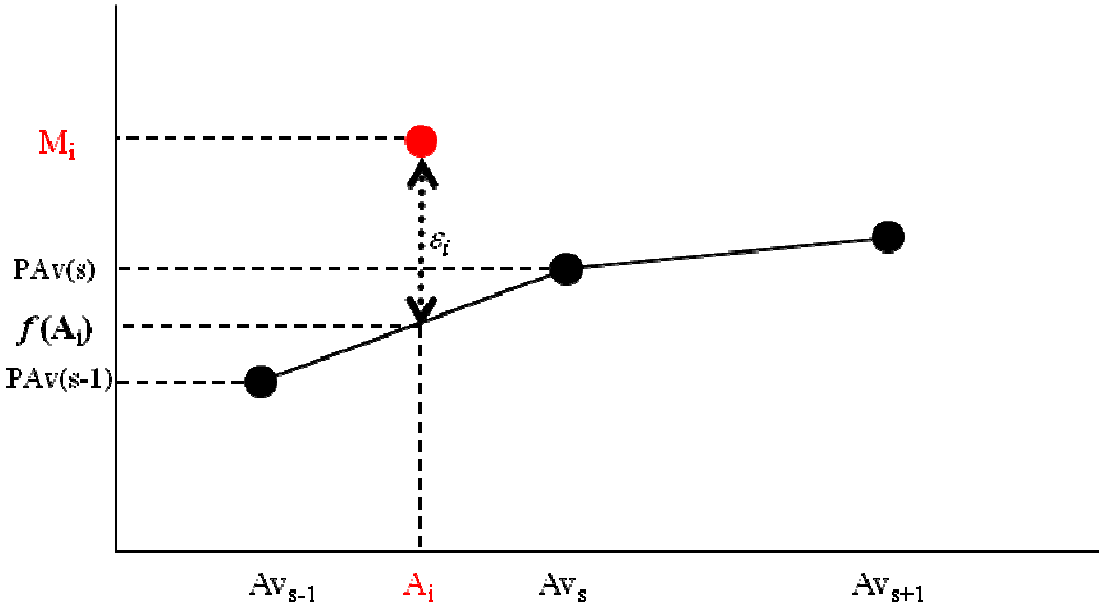

Figure 3. Bias reduction by partial averages on MA-plot.

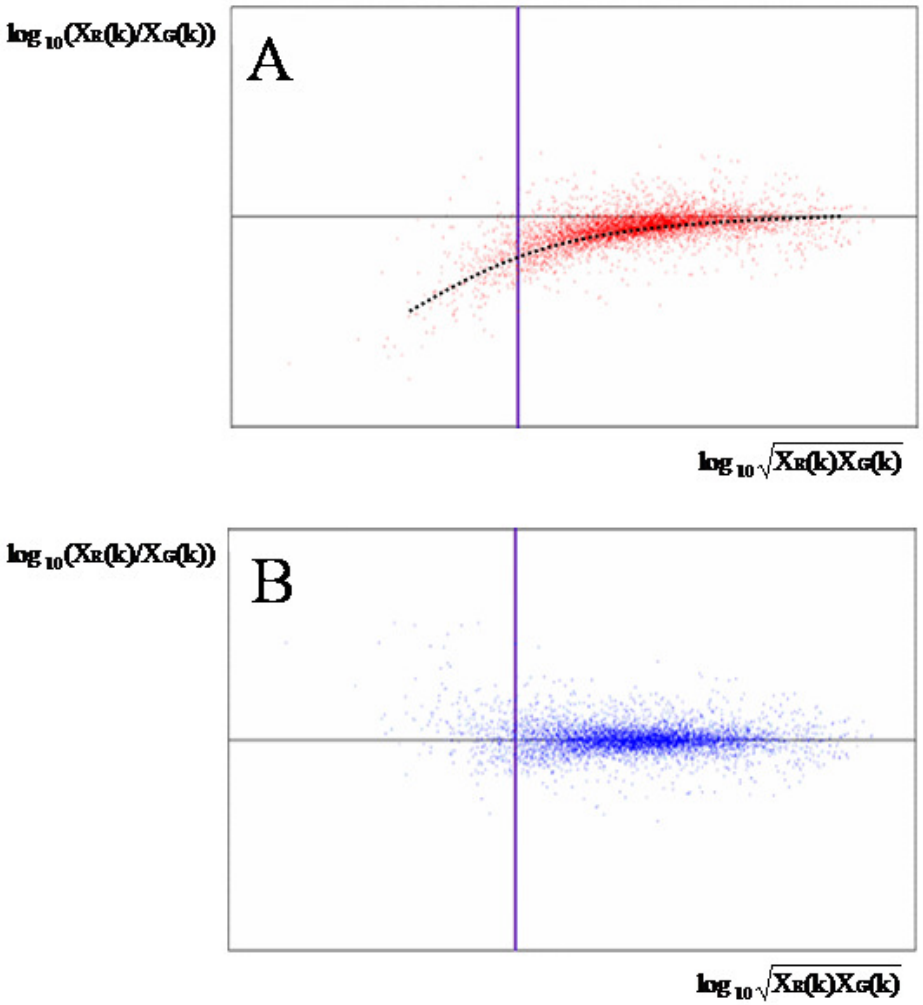

Figure 4. MA plots (A) before and (B) after the normalization of the logarithmic ratio of expression intensity by TREBAX.

3.1.3.3 Prediction of co-expressed gene clusters

If multiple genes are transcribed into a single mRNA, correlations of expression profiles among these genes can be observed. So, I try to develop a procedure for predicting TUs using correlations of expression profiles between genes in the same directon. Figure 5 shows that co-expressed gene clusters were predicted based on expression profiles and genomic locations (Fig. 5). The expression profile of the *i*th position gene is represented by vector $\mathbf{x}_i$, consisting of logarithmic ratios for microarray experiments:

$$\mathbf{x}_i = (x_{i1}, x_{i2}, ..., x_{iN})$$

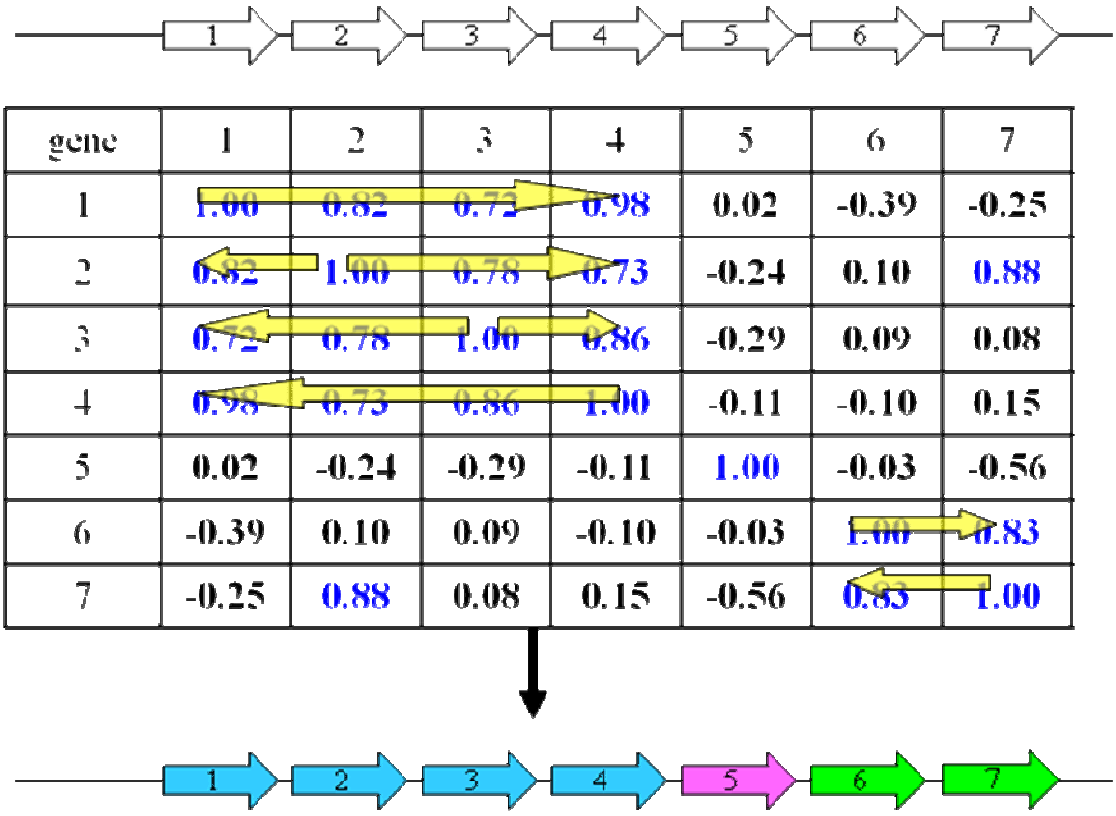
where N is the number of microarray experiments.

The procedure for predicting co-expressed gene clusters is as follows: I selected a directon. The genes were denoted by $g_1, g_2, \ldots g_i, \ldots, g_M$ from their 5' to 3' termini. Here, g_i and g_{i+1} (i = 1, 2, …, M-1) are adjacent genes on the same DNA strand. First, Pearson correlation coefficients (r_{st}) were estimated for all pairs of vectors $\boldsymbol{x}_s$ and $\boldsymbol{x}_t$ (s = 1, 2, …, M; t = 1, 2, …, M) as follows:

$$r_{st} = \frac{\sum_{j=1}^{N} (x_{sj} - \overline{x_s})(x_{tj} - \overline{x_t})}{\sqrt{\sum_{j=1}^{N} (x_{sj} - \overline{x_s})^2 \sum_{i=1}^{N} (x_{tj} - \overline{x_t})^2}} .$$

Here, $\overline{x_s}$ and $\overline{x_t}$ are average values of each vector.

Second, a pair of genes was assigned to a candidate group G_s as follows: All the genes $g_{s+1}, g_{s+2}, \ldots, g_{s+Ts}$, whose correlations $r_{s(s+1)}, r_{s(s+2)}, \ldots, r_{sTs}$ were statistically significant in a t-test at the 5% significance level, were classified into G_s. In the same manner, all the genes $g_{s-1}, g_{s-2}, \ldots, g_{s-Us}$, whose correlations $r_{s(s-1)}, r_{s(s-2)}, \ldots, r_{sUs}$ were statistically significant in a t-test at the 5% significance level, were also classified into G_s. Thus, altogether T_s+U_s+1 genes were classified into group G_s. By comparing all members of group G_s (s = 1, 2, …, M), I counted the number of groups consisting of identical members among G_s (s = 1, 2, …, M) and selected the group having the highest count as the first co-expressed gene cluster T_1. After excluding the T_1 genes from all the groups (g_1 to g_M), I selected the next-highest identical group as the next co-expressed gene cluster T_2. This procedure was carried on until the number of members in the cluster T_v (v = 1, 2, …, M) was zero, or until all positions j (j = 1, 2,…, M) were occupied by genes belonging to the cluster T_v.



gene	1	2	3	4	5	6	7
1	1.00	0.82	0.72	0.98	0.02	-0.39	-0.25
2	0.82	1.00	0.78	0.73	-0.24	0.10	0.88

Figure 5. Prediction method of co-expressed gene clusters. In the gene matrix of Pearson correlation coefficients, blue figures indicate statistically significant values in a t-test at the 5 % significance level, and a yellow arrow indicates a series of genes with statistical significance between a gene at the starting edge of the arrow and genes in the arrow shaft (upper figure). A series of the same color genes indicates co-expressed gene cluster (lower figure).

3.1.3.4 Expression analysis of σ-factor and TF deletion mutants of *B. subtilis*

3.1.3.4.1 Detection of significant expressed genes

The normalized fluorescence intensity data were analyzed using a one-sided test to compare the results of the σ-factor and TF deletion mutant to the control samples, and genes whose expression exceeded the threshold were regarded as σ-factor and TF regulated genes. In lower one-sided tests, I considered genes of decreased expression as being up-regulated by the σ-factor and TF, whereas genes of increased expression were considered as down-regulated by the σ-factor and TF in upper one-sided tests.

3.1.3.4.2 False discovery rate procedure

For detecting proportion of false positive data in the significant data of σ-factor and TF mutant arrays identified in one-sided tests, I used the false-discovery rate (FDR), an alternative approach to multiple testing [Benjamini and Hochberg 1995]. On the assumption that I conducted m multiple tests, the null hypothesis that each gene is differentially expressed is true for m_0 tests, and the alternative hypothesis is true for m_1 ($= m - m_0$). Among the m_0 null hypotheses, U hypotheses were declared false-negative and V ($= m_0 - \mathrm{U}$) hypotheses were declared true-positive. Among the m_1 alternative hypotheses, T hypotheses were called true-negative and S ($= m_1 - \mathrm{T}$) hypotheses were called false-positive. R ($= \mathrm{V} + \mathrm{S}$) is the total number of hypotheses rejected and an observable random variable. The FDR was defined as

$$\pi_0 = \begin{cases} E(\dfrac{\mathrm{V}}{\mathrm{R}}) & (\mathrm{R} > 0) \\ 0 & (\mathrm{R} = 0) \end{cases}$$

where E(V/R) means expectation values of V/R. I thus regarded R (1 - π_0) as the number of true active genes (Table 1).

Table 1. Number of intrinsic errors from m null hypothesis tests of a set of genes

	Declared non-significant	Declared significant	Total
Null hypothesis	**U**	**V**	m_0
Alternative hypothesis	**T**	**S**	m_1
Total	m - **R**	**R**	m

3.1.3.5 Identification of promoter sequences by PWM

To estimate σ-factor and TF binding sites, I used position-weight matrices (PWMs). PMWs make it possible to search for sequences highly homologous to those known to be recognized by σ-factors and TFs using PWM. First, I prepared datasets of training sequences consisting of experimentally determined promoters from DBTBS and a reference [Sonenshein et al. 2001], which were aligned on the basis of their consensus regions. PWMs for individual σ-factors and TFs were constructed by the frequencies F_{Ak}, F_{Tk}, F_{Gk}, and F_{Ck} of the four nucleotides (X = A, T, G, C) in the kth position, including the consensus regions and the five bases upstream and downstream.

I determined the score by multiplying all the frequencies corresponding to a given sequence. Second, the thresholds for the binding sites were determined as follows: 4,000 DNA sequences respectively comprising 300 nucleotides were generated randomly taking the GC content of *B. subtilis* into consideration. The threshold was defined by the upper value of the lowest 95% of the maximum scores in individual DNA sequences. Third, within the 300-nucleotide sequence upstream of the protein-coding region, individual σ-factor and TF binding sites were predicted by the maximum PWM score above the threshold because about 95% of these binding sites were known to exist in the regions. I chose optimal matrices for each random sequence, and regarded sequences that exceeded the threshold as being regulated by the σ-factor and TF. Therefore, I used these sequences to search for other sequences highly similar to those recognized by kth gene regulatory protein. This was done by calculating scores, $S(k)_{p(k)}$, or $S(k)_{p(k)\,q(k)}$ for the partial sequences composing $p(k)$ nucleotides for single biding site, or for $p(k)$ and $q(k)$ nucleotides for two binding sites in the stretch of 300 nucleotides upstream of the protein-coding regions of all *B. subtilis* genes. Here, the index k corresponds to kth gene regulatory protein. The scores were estimated using the following equations.

$$S(k)_{p(k)} = \prod_{i=1}^{p(k)} F(k)_{Xi} \qquad \text{(for a single binding site),}$$

$$S(k)_{p(k)q(k)} = \prod_{m=1}^{p(k)} F(k)_{Xm} + F(k)_{int(r)} + \prod_{n=1}^{q(k)} F(k)_{Xn} \qquad \text{(for two binding sites).}$$

Here, x_i is any nucleotide, A, T, G or C and $F(k)_{int(r)}$ is the frequency at interval between these sites,

and *int(r)* is nucleotide number. Sequences whose scores exceeded a threshold were regarded as σ-factor and TF binding sites.

In the case that the PMW for *k*th gene regulatory protein consisting of 5 nucleotides is given by

$$\begin{pmatrix} F(k)_{A1} & F(k)_{A2} & F(k)_{A3} & F(k)_{A4} & F(k)_{A5} \\ F(k)_{T1} & F(k)_{T2} & F(k)_{T3} & F(k)_{T4} & F(k)_{T5} \\ F(k)_{G1} & F(k)_{G2} & F(k)_{G3} & F(k)_{G4} & F(k)_{G5} \\ F(k)_{C1} & F(k)_{C2} & F(k)_{C3} & F(k)_{C4} & F(k)_{C5} \end{pmatrix}.$$

$S(k)_{p(k)}$ for a nucleotide sequence ATGCG is calculated by,

$$\begin{aligned} S(k)_{p(k)} &= \prod_{i=1}^{5} F(k)_{Xi} \\ &= F(k)_{A1} F(k)_{T2} F(k)_{G3} F(k)_{C4} F(k)_{G5} \end{aligned}$$

3.1.4 Results and Discussion

3.1.4.1 The integrated strategy for TU prediction

There are at least 18 different σ factors that direct RNA polymerase, and a large number of sequence-specific DNA binding proteins that play various roles in controlling gene expression, as promoter activators or repressors in *B. subtilis* [Fujita and Fujita 1987; Henikoff et al. 1988]. PWMs for 11 σ-factors and 17 TFs were constructed as shown in Figure 6. Therefore new consensus sequences for the 11 σ-factors and 17 TFs are offered in this study. Consensus sequences for the σ-factors in Table 2 are fairly well consistent with the previous reports in spite of using different training data [Sonenshein et al. 2001], In consensus sequences for 11 σ-factors, these sequences for σD, σL and σW are the same formations between my results and the previous data by Sonenshein et al [2001]. The consensus sequences for σE and σK at the -35 region in this study are the same as the previous data, and the sequences at the -10 region in my results and the past data are "CATAyawT" and "cATAcanT" respectively in σE, and "CATAtnmT" and "CATAnnnT" respectively in σK (Table 2) [Sonenshein et al. 2001]. In these sequences for σE and σK at the -10 region, the 5^{th} and 7^{th} bases in my result differ from those in the past data. In the other σ-factors, these sequences at both the -35 and -10 regions differ slightly from the previous data about a couple of bases, but these different bases mostly exist in less conserved positions of the consensus sequences (Table 2). 77.6% of the bases in the consensus sequences and 95.7% of the bases in the highly conserved positions of the previous results are conserved in my results. Comparing my results with the past data, I used more σ-factor binding sequences for my training data set than those used in the past results, so my results could be proper results particularly in less conserved positions of the consensus sequences.

In the σ-factor and TF binding site searches using PWM, I found putative binding sites regulated by each σ-factor and TF below the thresholds and detected many binding sites in the known binding sites identified by experiments (Table 3). In addition, I use these data for the feature analysis, and Figure 7 shows a comparison of coverage (Fig. 7A) and sensitivity (Fig. 7B) between the 1% and 5% thresholds. I was able to narrow down the candidates for σ-factor and TF binding sites to 26.1% of the candidates (i.e. from 431 to 110 sites) when I changed the threshold from 5% to 1% (Fig. 7A). On the 5% threshold, I identified an average of 78% known binding sites, and an average of 69% binding sites on the threshold of 1% (Fig. 7B). Thus, the average

difference of detecting known binding sites is 9%, corresponding to 3.5 binding sites, by changing the threshold from 5% to 1%. Furthermore, in most gene regulatory proteins I could efficiently narrow down candidates for the binding site, and found that the number of known binding sites detected below each of the thresholds hardly changed. Therefore, I took these PWM analyses at the threshold of 1%.

In several gene regulatory proteins, particularly those having a large number of binding sites, the number of detected known binding sites decreased, as I took the lower threshold. This may be because the TFs have multiple binding sites, upstream of protein-coding regions, whose binding specificities are different [Zheng and Losick 1990; Hamoen et al. 2001]. In the detection of genes regulated by σ-factors and TFs, I found candidate up-regulated genes for 11 σ-factor and 17 TFs, and candidate down-regulated genes for 17 TFs (Table 4). This statistical procedure to identify differentially expressing genes involves a multiple comparison problem because I perform as many hypothesis tests as the number of the candidate genes in microarray. Therefore, I used the false discovery rate (FDR) procedure to remove false-positive data from the candidates of significant expression change data and narrow the candidates for genes regulated by each of the σ-factors and TFs [Pawitan et al. 2005]. FDR is a concept of testing error that is defined as the expected value of the proportion of the inactive genes among the detected genes [Jung 2005]. This enabled us to improve the prediction of candidates for genes regulated by σ-factors and TFs to an average of 33% (range, 12%-49%). In the analyses of genes regulated by each of the σ-factors and TFs, I identified significant microarray data by calculating the *P*-value for each gene, and used the FDR process to eliminate pseudo-positive samples in the detected data. I decreased the candidates for genes regulated by the σ-factors and TFs using this method (Table 4) and was able to efficiently narrow the TU candidates regulated by each of the σ-factor and TFs and detect known operons in the combination approach with FDR control. FDR is a natural scale for work on statistical problems of controlling error rates, and my proposed method could be a useful predictor for searching for TUs on whole genomes.

I then integrated these analyses, and present a comparison of coverage (Fig. 8A) and sensitivity (Fig. 8B) between two integrated conditions (i.e. a 5% threshold at PWM and a 5% threshold in the deleted mutant array without FDR, and a 1% threshold at PWM and a 5% threshold in the deleted mutant array with FDR).

I was able to narrow down the candidate genes composing TUs at the 5% PWM without FDR

to 24.5% of the candidates (i.e. from 194 to 50 genes) when I changed the condition from the PWM 5% threshold without FDR to the PWM 1% threshold with FDR, with 87.1% of genes detected at 5% PWM without FDR also being detected at 1% PWM with FDR. Thus, the candidates can be effectively narrowed without remarkable loss of regulation-known genes under the condition of 1% PWM with FDR. The σL, PerR, and PurR TUs were efficiently detected. Regarding the σL TUs in particular, I could narrow down the 63 TU candidates for the PWM 5% threshold to 9 candidates for the PWM 1% threshold with FDR control without any loss of sensitivity. The detected TUs for the 1% PWM with FDR and known TUs regulated by each of the TFs are listed in Table 5.

Previous predictions of TUs or operons have been based on homologous gene pairs on other genomes, intergenic distance, functional categories and conserved gene clusters among multiple organisms [Salgado et al. 2000; Ermolaeva et al. 2001; Wang et al. 2004; Westover et al. 2005]. In contrast, this approach has the advantage of allowing us to predict gene cluster, without having to depend on homologous gene arrangement in other genomes or functional classification of orthologous genes. I can therefore identify gene clusters at different phases of the life cycle and under various circumstances. The method may be applicable to understanding new functional clusters on the whole genome. However, some identified gene clusters differed from known operons in the number of genes that composed the units. A number of opportunities exist for improving my prediction of gene clusters. Recent studies have used high-density tiling arrays and identified expression in short chromosomal regions [Ishkanian et al. 2004; Bertone et al. 2004]. Such arrays may be helpful to recognize borders of each gene cluster.

As a result, I can detect variously-sized TUs, so the entire TU structure on the *B. subtilis* genome can be estimated on the basis of these predicted TUs. At the 1% PWM with FDR, I can pick 2,183 genes composing 892 TUs, which include known operons, from the complete *B. subtilis* genome. The average size of the polycistronic TU is 3.71 genes, which is comparable in size to those in *Staphylococcus aureus* (3.47 genes) [Wang et al. 2004] and in *E. coli* K12 (3.41 genes) [Salgado et al. 2000]. Distribution of the TUs to the number of genes is almost identical between *B. subtilis* and *S. aureus* (Fig. 9) [Wang et al. 2004]. Thus the operon organization of those two Gram-positive bacteria are fundamentally identical and are approximated by power-law equations, where the correlation of the double logarithm linear relation between the numbers of genes and of TUs composed by the genes is -0.98 in *S. aureus* and -0.97 in *B. subtilis*.

[a] **U** and **D** refer to genes that are up- and down-regulated, respectively, in the presence of the σ-factor and TF. Figures in parentheses indicate number of genes regulated by the σ-factors and TFs.

[b] All data were identified under 1% threshold in PWM and 5% threshold in deletion mutant array with FDR. Among these genes, the known genes regulated by the σ-factor and TF are indicated in bold.

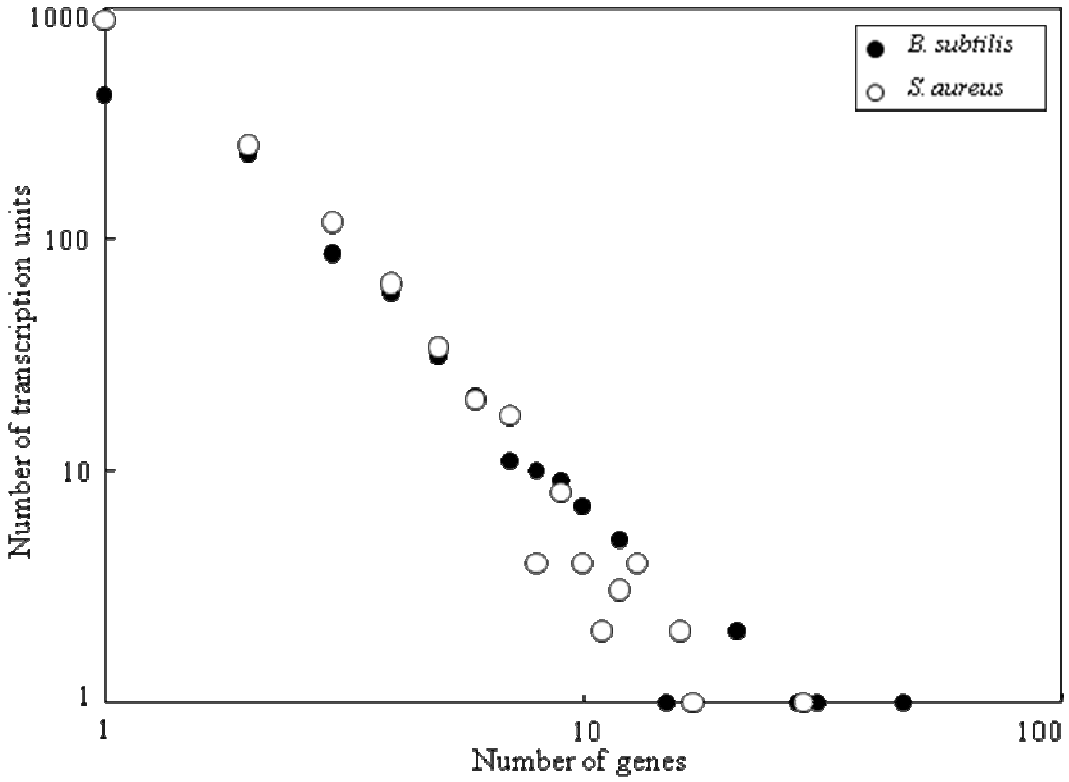

Figure 9. The relationship between the number of TUs detected in the present study and the number of genes composing the TUs.

3.1.4.2 Functions of TUs in *B. subtilis*

3.1.4.2.1 COG functional classification of genes regulated by σ-factors and TFs

Using the TU data, I examined the transcriptional regulation of genes by 11 σ factors whose promoter sequences have been characterized. The properties of individual σ factors are as follows: five σ factors (σE, σF, σG, σH, σK) regulate sporulation through morphological stages that involve the conversion of the growing cell to a two-cell sporangium, which ultimately proceeds to a single spore; σB mediates the general stress response, and more than 150 protein-coding genes for general stress belong to the σB regulon [Hecker et al. 1996]; σL mediates cold-shock adaptation and regulation of the acetoin catabolic pathway [Wiegeshoff et al. 2006]; σD regulates flagellar synthesis, motility, and chemotaxis [Marquez-Magana and Chamberlin 1994]; σM mediates salt resistance [Horsburgh and Moir 1999]; and σX and σW play modulatory roles in extracytoplasmic function [Turner and Helmann 2000]. All the regulative relations of the 11 σ factors and 17 TFs to targeted genes are listed in Table 5, making it possible to characterize individual σ factors according to the genes they target. Therefore, I classified genes belonging to each of the TUs into 19 COG (clusters of orthologous groups of proteins) functional categories [Tatusov et al. 1997] for estimating the general roles of the σ factors and TFs in cellular processes (Fig. 10).

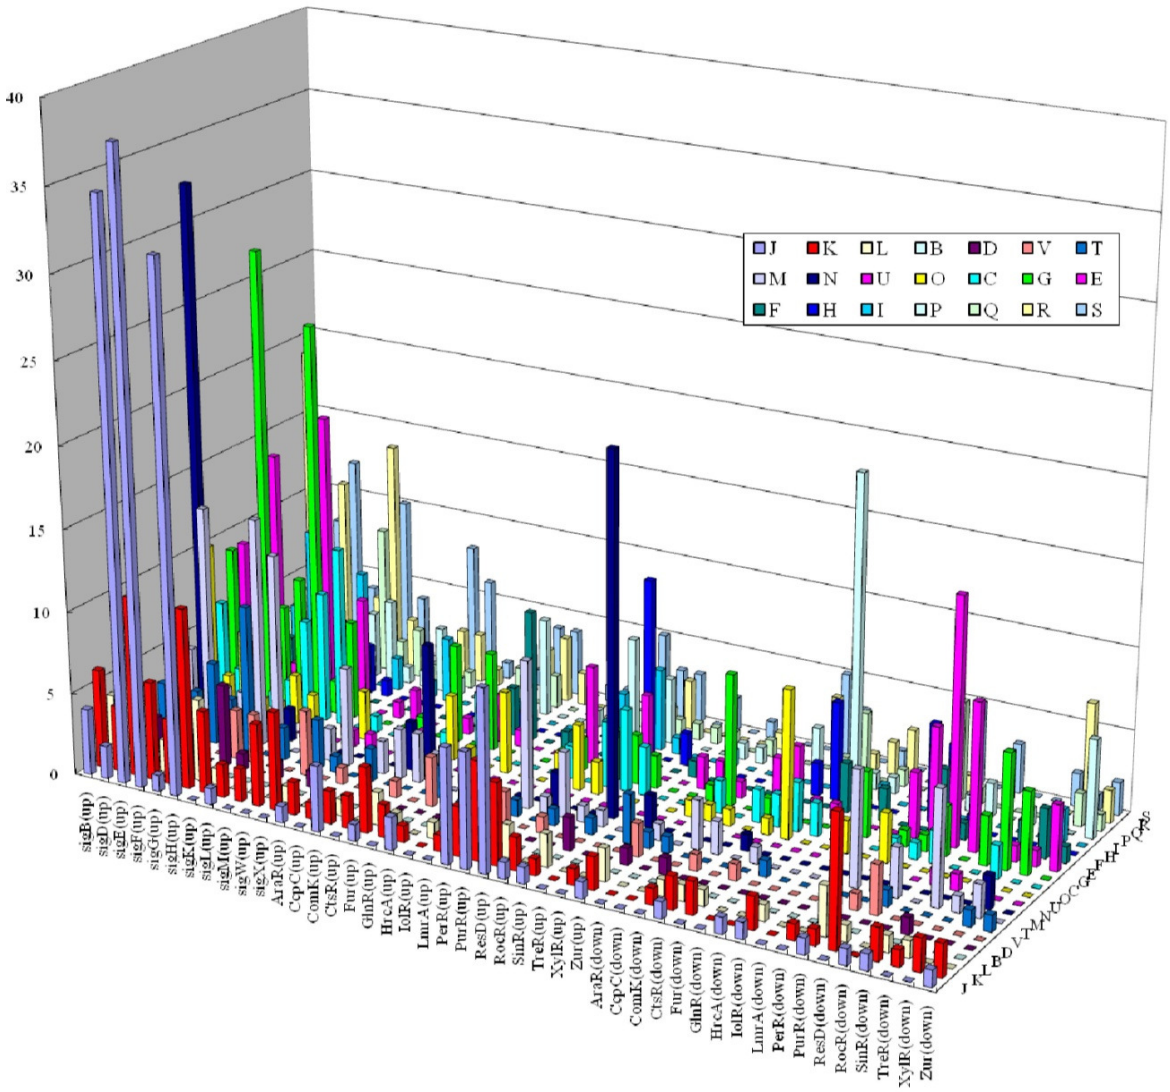

Figure 10. Classification of genes regulated by each σ-factor and TF by COG functional categories.

One-letter abbreviations use used for the functional categories: J, translation, ribosomal structure and biogenesis; K, transcription; L, DNA replication, recombination and repair; B, Chromatin structure and dynamics; D, cell division and chromosome partitioning; V, Defense mechanisms; T, signal transduction mechanisms; M, cell envelope biogenesis and outer membrane; N, cell motility and secretion; U, Intracellular trafficking and secretion; O, posttranslational modification and protein turnover, chaperones; C, energy production and conversion; G, carbohydrate transport and

metabolism; E, amino acid transport and metabolism; F, nucleotide transport and metabolism; H, coenzyme metabolism; I, lipid metabolism; P, inorganic ion transport and metabolism; Q, secondary metabolite biosynthesis, transport and catabolism; R, General function prediction only; S, Function unknown.

3.1.4.2.2 Functional relationships between categories of genes regulated by σ-factor and TFs

The similarity of the roles in cellular process between individual σ-factor and TFs was estimated using Pearson correlation coefficients for the number of genes belonging to each of the COG categories (Fig. 11).

The five σ factors associated with regulation of the sporulation process can be classified into three groups corresponding to the sporulation process Stage 0-III (σH, σF and σE) characterized by category [J; translation, ribosomal structure and biogenesis], Stage IV (σG) characterized by the category [G; carbohydrate transport and metabolism], and Stage V (σK) characterized by category [M; cell envelope biogenesis and outer membrane]. Gene expression under the σG control occurs in the prespore, and the main functions are to protect the spore from several hazardous conditions, high osmotic pressure [Tovar-Rojo et al. 2003], UV radiation and dry heat [Setlow 1995], and to prepare the spore for germination and outgrowth [Hilbert and Piggot 2004]. In this process, σG regulates carbohydrate content in the cell, for example, by activating expression of the glucose dehydrogenase operon [Nakatani et al. 1989], controlling metabolism of the tricarboxylic acid cycle [Magill et al. 1996] and glucose uptake [Lorca et al. 2003]. σK is synthesized and becomes active in the mother cell, and directs formation of the spore coat and spore maturation [Hilbert and Piggot 2004]. Therefore, these previous experimental studies are consistent with the present results. Moreover, I can observe that each TF in a cluster has one of the frequently detected functional categories (Fig. 11). The AraR protein is well known as a negative regulator of the L-arabinose metabolic operon [Sa-Nogueira and Mota 1997], and most of the genes negatively regulated by AraR belong to [G] (Fig. 10). Almost all the genes up-regulated by SinR are in category [N], which consists of proteins controlling cell motility and secretion, while the down-regulated genes belong to category [M], which consists of proteins operating cell-wall and membrane biogenesis (Fig. 11). ComK synthesis is regulated by a series of reactions that involve quorum sensing; SinR is one of the activators in this cascade, acting negatively on *rok* transcription [Hoa et al. 2002], and is known to be a potent repressor of biofilm formation [Kearns et al. 2005]. Thus, the analysis presented here agrees well with previous experimental data and enables us to assess the roles of the σ factors and TFs in cellular processes.

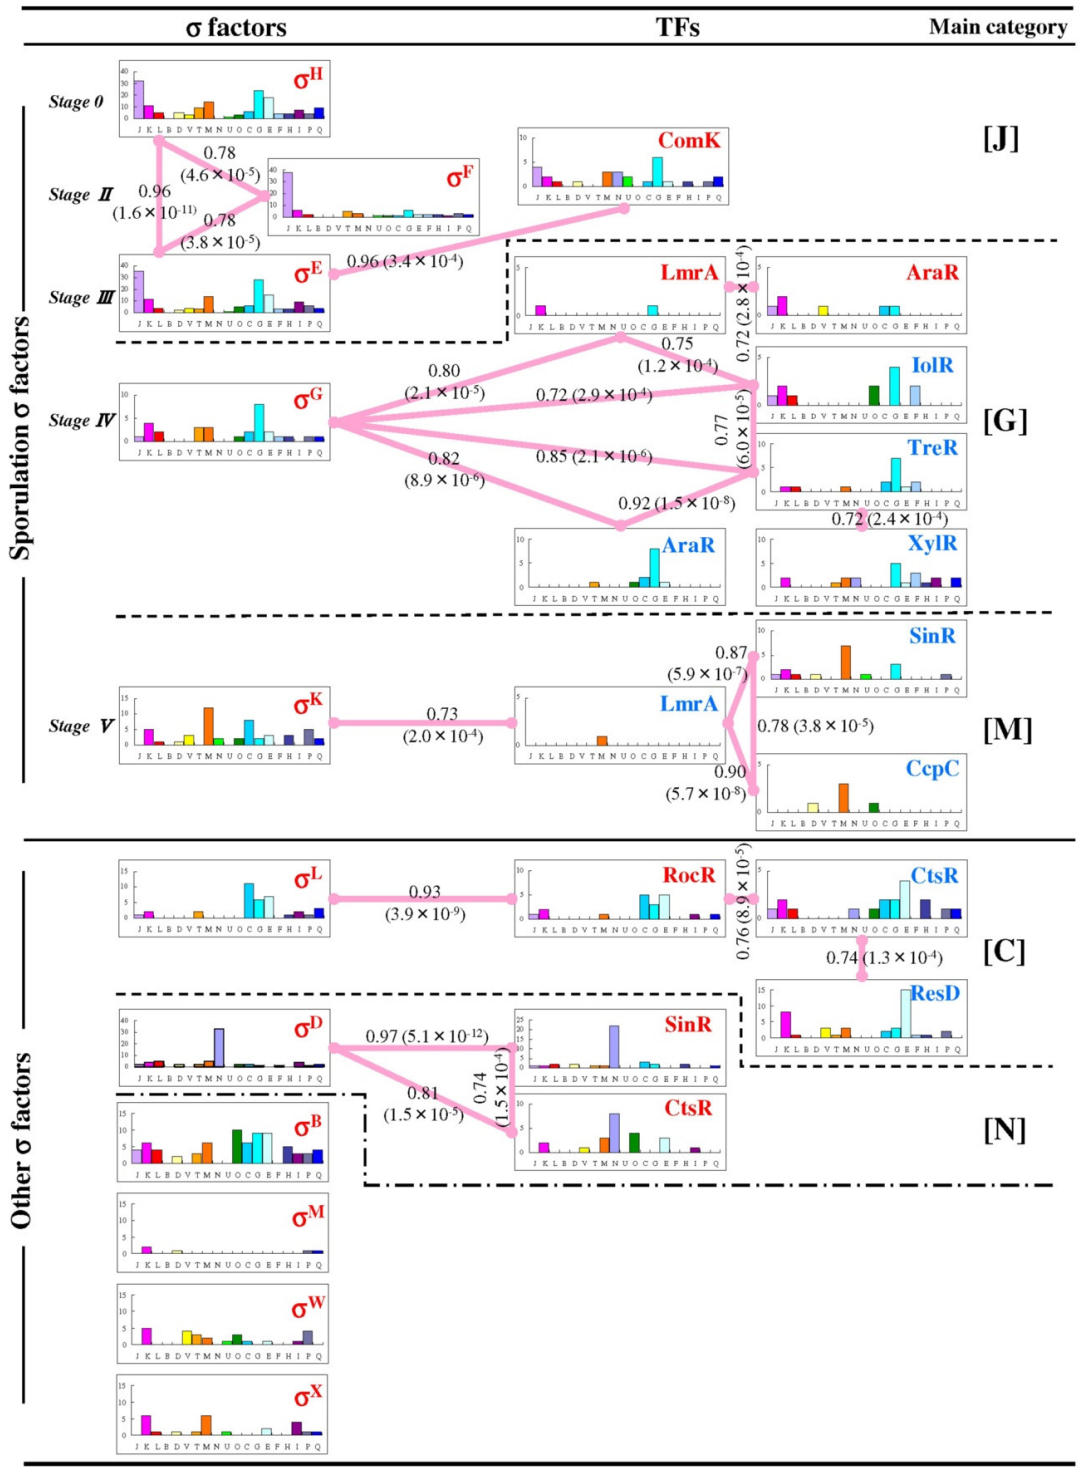

Figure 11. Clustering of σ-factor and TFs based on the functional similarity of genes composing the TUs. For

clustering of σ-factor and TFs, Pearson correlation coefficients among σ-factor and TFs were calculated using the frequencies of genes belonging to each of the COG categories. I regarded groups of σ-factors and TFs that have correlation coefficients above 0.70 (solid lines) as the clusters. Pearson correlation coefficients and P-values in the parentheses are represented on the solid lines. The main category represents the COG category into which the most genes regulated by each of the σ-factors and TFs in the clusters are classified. All data were identified under PWM with 1% threshold and FDR control. One-letter abbreviations show in Figure 10.

3.1.4.2.3 PCA for functions of genes composing TUs

In addition, the genes targeted by σ factors and TFs are classified into 36 categories based on functional classification of the *B. subtilis* protein-encoding genes [Sonenshein et al. 2001] to examine the role similarities among them based on *B. subtilis*-specific gene functions such as the endospore-formation process. I then show the projection of σ factors and TFs in the largest two principal components (Fig. 12A) and factor loadings of individual categories, indicating the contribution of the category frequencies to the two principal components based on the frequencies of the 36 categories (Fig. 12B). I observe a small cluster composed of σD, CtsR and SinR (a broken line circle in Fig. 12A), which is consistent with the result in Figure 11. Here, σD is the σ28-form subunit of RNA polymerase, and many σD-dependent genes are known to be necessary for flagellar synthesis and motility functions [Mirel and Chamberlin 1989]. In addition, CtsR controls the expression of heat-shock proteins that are required for stress tolerance and growth at high temperature [Derre et al. 1999], and play essential roles in competence development and motility [Msadek et al. 1998]; SinR also regulates the development of genetic competence and motility [Guillen et al. 1989]. Thus, the roles of these three TFs in cellular processes are associated with motility, and those are plotted in the same region of the cluster characterized by category [1.6, motility and chemotaxis] (Fig. 12AB). This result shows that roles of σ-factors and TFs can be estimated by the principal component analysis (PCA) based on comprehensive searches for functions of genes composing these TUs.

It can also be seen in another cluster composed of Fur, Zur, IolR, PurR, RocR, and GlnR (a broken line circle in Fig. 12A). Fur and Zur regulate the expression of ABC transporters and both TFs control iron and zinc uptake and homeostasis pathways in response to available metals [Gaballa and Helmann 1998; Ollinger et al. 2006]. IolR and PurR also control transport systems. IolR regulates genes encoding inositol transporters and inositol uptake [Yoshida et al. 1997], while PurR regulates purine transport, metabolism, and biosynthetic pathways [Ebbole and Zalkin 1989]. In this cluster, RocR and GlnR relate to controlling nitrogen sources: RocR controls arginine catabolism [Gardan et al. 1995] and the arginase pathway in which arginine is converted to glutamate [Belitsky and Sonenshein 1999], while GlnR regulates responses to nitrogen availability, such as nitrogen metabolism [Fisher 1999] and assimilation [Magasanik 1982].

Based on these previous studies, this result shows that I can cluster together homeostatic regulation σ-factors and TFs (Fig. 12A). Moreover, σ factors that regulate sporulation (σE, σF, σG,

σH, σK) tend to exist near the y-axis in the region of lower first-principal component (PC1) values with negative PC2 values, and TreR, SinR, and CcpC are also plotted near the σ factors (Fig. 12A). TreR regulates trehalose as the sole carbon and energy source of *B. subtilis* during spore outgrowth [Kennett and Sueoka 1971], while SinR controls regulatory genes involved in the early stages of sporulation [Cervin et al. 1998]. Thus, sporulation-related TFs tend to have lower PC1 values and negative PC2 values, which may be evidence that category [1.9; sporulation] and [1.4; germination] are plotted in the area (Fig. 12B). Therefore, CcpC is known to be a regulator of the tricarboxylic acid cycle genes [Hanson and Cox 1967], but may also have a function in regulating sporulation genes. These results demonstrate that the combined approach is very useful for specifying all of the TUs on the *B. subtilis* genome.

In the present study, I identified various sizes of TUs regulated by each σ-factor and TF and part of TUs overlapped by some genes. There are two types of overlap pattern between adjacent TUs. One type is that some short TUs compose parts of a long TU. In the structure, I detected gene clusters consisting of part of well-known operons (*yabPQ* regulated by σE and *divIC-yabR* regulated by σX in *yabMNOPQ-divIC-yabR* operon, *nasDEF* regulated by GlnR in *nasBCDEF* operon, *yjmEFGHIJ* regulated by σE in *yjmABCDEFGHIJ* operon, *spoVE-murG* regulated by σE in *murE-mraY-murD-spoVE-murG-murB-divIB-ylxWX-sbp* operon, *xynB* regulated by XylR in *ynaJ-xynB* operon and *yoxB-yoaA* regulated by σB in *yoxCB-yoaA* operon mentioned in Table 5). Part of them are known to be regulated by internal promoters and to constitute functional components [Gao et al. 2006], for instance, *yabPQ* regulated by σE that plays an important role in synthesis of the spore cortex and coat [Asai et al. 2001], and *divIC-yabR* regulated by σX which is essential for the initiation of vegetative septum formation [Huang and Helmann 1998; Levin and Losick 1994] in *yabMNOPQ-divIC-yabR* operon. Therefore, these gene clusters separated by internal promoters are likely to be functional units. The other type is that tail region of upstream TU overlaps with head region of downstream TU. These overlapping regions should belong to upstream or downstream TU, and therefore there is promoter for the downstream TU at edge of upstream in the region or there is terminator for the upstream TU at edge of downstream in the region.

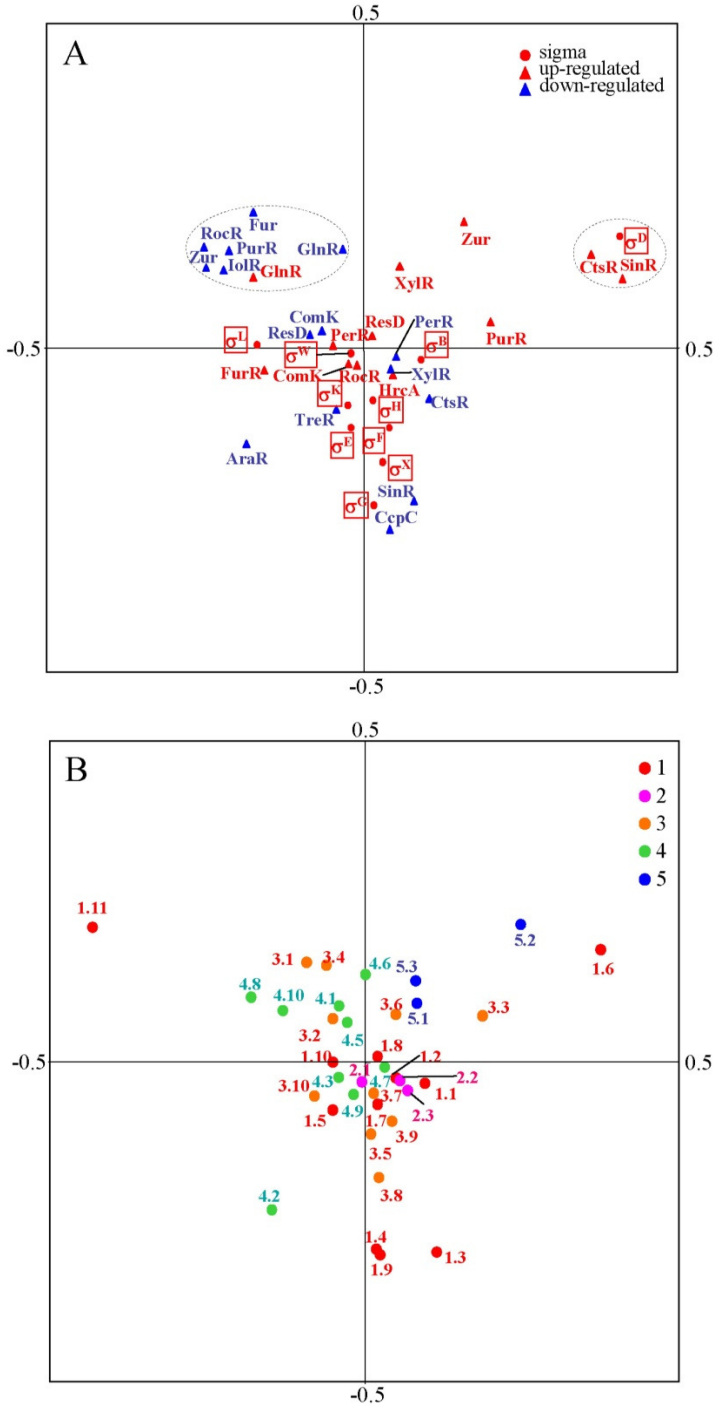

Figure 12. Score plots for PCA of σ-factors and TFs and functional categories. (A) Score plot based on frequencies of σ-factor and TF functions. (B) Score plot based on frequencies of functional classification of the *B. subtilis*

protein-encoding genes. Abbreviations for the functional categories: 1, cell envelope and cellular processes [1.1, adaptation to atypical conditions; 1.2, cell division; 1.3, cell wall; 1.4, germination; 1.5, membrane bioenergetics (electron transport chain and ATP synthase); 1.6, motility and chemotaxis; 1.7, protein secretion; 1.8, sensors (signal transduction); 1.9, sporulation; 1.10, transformation/competence; 1.11, transport/binding proteins and lipoproteins]; 2, cytochromes [2.1, cytoplasmic; 2.2, membrane-bound; 2.3, other cytochromes]; 3, information pathway [3.1, competence regulatory; 3.2, detoxification; 3.3, DNA packaging and segregation; 3.4, DNA replication; 3.5, DNA restriction/modification, repair and recombination; 3.6, protein folding; 3.7, protein modification; 3.8, protein synthesis; 3.9, RNA modification; 3.10, RNA synthesis]; 4, intermediary metabolism [4.1, antibiotic production; 4.2, carbohydrates and related molecules; 4.3, degradation; 4.4, general function prediction; 4.5, metabolism of amino acids and related molecules; 4.6, metabolism of coenzymes and prosthetic groups; 4.7, metabolism of lipids; 4.8, metabolism of nucleotides and nucleic acids ; 4.9, metabolism of phosphate; 4.10, metabolism of sulfur]; 5, other functions [5.1, antibiotic production; 5.2, phage-related functions; 5.3, transposon and insertion elements].

3.2 Identification of *B. subtilis* operon using comparative genomic approach

3.2.1 Introduction

There has been a variety of clues for operon prediction, and many studies have used phylogenetic information as a promising means of predicting operon structure [Bergman et al. 2007; Edwards et al. 2005]. In prokaryote genomes, gene orders and orientations are conserved across a variety of genomes and these adjacent genes that are found in the same order in multiple genomes are likely to be co-transcribed [Ermolaeva et al. 2001]. The conservation of gene grouping is likely to occur by sharing the gene clusters among evolutionarily related organisms and by horizontal transfer of the genes, and thus the formation of the operons remains widely the same and gene orders in the operons are conserved across species.

In many cases of phylogenetic analyses including this study, the basic local alignment search tool (BLAST) has been frequently used for searching the most similar sequences from the DNA and protein sequence database [Altschul et al. 1997]. BLAST is a heuristic program that is written to compare protein or DNA queries with protein or DNA databases. This approach to finding the sequences in the databases most similar to a query is performed to calculate the pairwise score of the alignment between the query and every sequence in the databases [Altschul et al. 1990].

In this study, I used the *blastp* program [Altschul et al. 1997], which compares protein queries to protein databases and detected orthologous genes in 54 Gram-positive bacteria except *B. subtilis*. Using these data and my TU data, I determined the appropriate boundaries of TUs and predicted genome-wide operon structure in the *B. subtilis* genome.

3.2.2 Data

A set of 55 Gram-positive bacterium genomes were obtained from NCBI [NCBI FTP].

3.2.3 Methods

3.2.3.1 Identification of successive homologous gene clusters

Each of the gene sets of the bacterium genomes was compared to that of the *B. subtilis* genome and reversely the gene set of *B. subtilis* genome was compared to those of the 54 query genomes by BLASTP with the BLOSUM62 matrix and an E-value cut-off of 10^{-5}, and the genes which have the highest sequence similarity in the both results as the orthologous genes were considered (Table 6). A gene with no homologous in *B. subtilis* genome was considered absent in this genome.

3.2.3.2 Identification of *B. subtilis* operons

I considered genes that were the orthologs and were in series in the same direction with no intervening gene on a pair of the genomes as the successive homologous gene clusters. When plural operon candidates overlapped in *B. subtilis* genome, I compared the orthologous clusters with each of the operon candidates and counted numbers of preserved species. When the upstream candidate had higher score than the other, I regarded the upstream one as an operon. When the downstream candidate had higher score than the other, I supposed that there was internal promoter which regulated the downstream candidate and the promoter divided the upstream one and regarded the forward part of the upstream one and the downstream one as operons. Finally, I selected the suitable operons by these procedures and identified *B. subtilis* operon on the genome.

Protein refers to total number of proteins in the bacterium.

3.2.4 Results and Discussion

Conservation of gene order is one of the principal types of context information. On the *B. subtils* genome, there are 3,123 consecutive gene pairs in the same directions and some gene pairs are operon pairs (OPs) in polycistronic operons. Comparing interspecies conservation of *B. subtilis* known OPs (KOPs) to that of the other consecutive gene pairs in the same directions among Gram-positive bacteria, 59.8% orthologous gene pairs of KOPs existed in other Gram-positive bacteria but 60.3 % of consecutive gene pairs except KOPs are only in the *B. subtilis* genome (Fig. 13(B)). The average number of conserved species in KOPs among Gram-positive bacteria was approximately twice as many as the number in the consecutive gene pairs in the same directions except KOPs (Fig. 13(A)). Therefore, the conservation of gene order is a key to finding relationships between neighbor genes, and this taxonomical information is likely to support determination of operon organization in a target genome.

I used comparative genomic analysis for determining appropriate boundaries of TUs identified by the integrated analysis and determined genes belonging to these overlapping regions using complete genome sequence data of other Gram-positive bacteria (Table 6). Based on the analysis, I regarded the non-overlapping TUs and these determined TUs as *B. subtilis* operons and showed the operon map (Appendix A). Applying this approach, I narrowed the candidate genes composing operons down to 999 genes from 2,183 genes composing TUs (Table 5, Appendix B), and the difference between operons predicted in the present study and known operons in the *B. subtilis* genome indicates that most of the predicted operons are consistent with those reported (Fig. 14). This additional application identified 528 *B. subtilis* operons (Fig. 15A2) and I then searched functional constitutions of operons predicted in this study and experimentally derived operons by DBTBS functional classification of their gene products (Fig. 15). The results show that most operons categorized by the four major DBTBS classifications tend to be composed of mono-functional gene clusters. When these operons are categorized by the DBTBS classifications, 86% are composed of mono-functional genes and 12 % have two functions (Fig. 15A) and I then search detailed functional formations for the mono-functional operons (Appendix B). In the mono-functional operons categorized by the detailed functional classifications, a few operons are di-functional in structure but 94% or more in each of the classifications are made of the same functional genes. This result supports that operon structure is constructed by gathering the same functional genes in taxonomical evolution and suggests that operons work as functional units.

There are a few multi-functional operons, but the operons having the largest functions are tri-functional operons (Fig. 15A2).

In the tri-functional operons, I can detect some operons that are of different structures from experimentally derived operons; *trePARyfkO, acoABCLRyfjU, etfABysiBA and yolKJIsunTA*. The detected operon, *trePARyfkO*, is composed of the *tre* operon [Schock and Dahl 1996], and the *yfkO* gene. In the *tre* operon, it is deduced that TreP acts as a specific enzyme in trehalose transport and phosphorylation [Klein et al. 1995], *treA* encodes phospho-α–(1,1)-glucosidase which hydrolyzes trehalise-6-phosphate in the growth phase [Gotsche and Dahl 1995], and treR encodes a specific Tre repressor involved in regulation of the expression of the *tre* operon [Schock and Dahl 1996]. Thus the *tre* operon regulates the ability to utilize trehalose. The function of *yfkO* composing the detected operon is not well understood, but I can assume by sequential analysis that *yfkO* encodes nitroreductase which is an enzyme lowering the activation energy for a reduction reaction of nitro groups, so that YfkO may act on trehalose metabolism via catalyzing nitro substrates.

In the *acoABCLRyfjU* operon, the four gene string, *acoABCL*, is known as the *aco* operon that encodes the E1α, E1β, E2, E3 subunits of the acetoin dehydrogenase multi-enzyme complex. Acetoin is a carbon source for growth and acts as an external carbon storage material in exponential growth [Huang et al. 1999]. Transcription of the *aco* operon is regulated by carbon catabolite repression *via* CcpA which is a negative regulator of carbon utilization genes and is a positive effector of genes in biosynthesis and secretion of metabolites [Henkin 1996]. The CcpA exerts negative regulation binding to the catabolite-responsive element of *acoA* [Miwa et al. 2000] and directly regulates transcription of *acoR* located immediately downstream from the *aco* operon [Ali et al. 2001]. AcoR is a regulator of the expression of the *aco* operon in the presence of σL and induces acetoin expression [Ali et al. 2001]. Furthermore, *yfjU* at the end of the *acoABCLRyfjU* operon encoding small, acid-soluble protein unique to spores of *B. subtilis* is not found for the gene expression in the vegetative phase and appears to be expressed in the growth phase as the expression of the *aco* operon. Then previous structural analysis showed that there is no obvious transcription terminator between the immediately upstream gene, *acoR* and *yfjU* and there is a transcription terminator candidate sequence with symmetry following the gene, so they suggested that these genes may be co-transcribed [Cabrere-Hernandez et al. 1999]. Therefore, the *acoABCLRyfjU* operon is constructed by different functional genes (Fig. 15B), but these genes

may be assembled for regulation of the catabolic pathway in the growth phase and the two genes, *acoRsspH*, of the detected operon may work as an internal operon [Gao et al. 2006], following the previous study [Huang et al. 1999]. My result supports northern blotting data in the BSORF database showing *acoABCLRyfjU* and *acoRsspH* transcripts [BSORF].

Recent study by BLASTP sequence similarity search presumed the four genes, *etfABysiBA*, that encoded α- and β-subunits of electron transfer flavoproteins involved in fatty acid β-oxidation, a enzyme belonging to the enoyl coenzyme A hydratase / isomerase family, and a TF to negatively regulate the expression of *lcfA* operon genes respectively [Barabesi et al. 2007] and then each product of these gene acts in fatty acid degradation pathway [Matuoka et al. 2007]. Furthermore, these genes are known to compose the *lcfA* operon which consists of five genes, *etfABysiBAlcfA* [Wipat et al. 1996], and northern blotting analysis of *etfABysiBAlcfA* transcripts detected several sizes of transcripts, *lcfA*, *ysiA*, *ysiABetfBA* and *etfABysiBAlcfA* [Matuoka et al. 2007]. Therefore, my result can confirm that there is an internal operon, *etfABysiBA*, in the *lcfA* operon. As for *sunATyolIJK*, northern bolt analyses using *sunA*- and *sunT*-specific probes showed that the *sunA* gene is transcripted as a monocistronic mRNA and the *sunT*-probe hybridized to an approximately 4.3-kb transcript corresponding to the polycistronic transcription of *sunTyolIJK* [Serizawa et al. 2005]. These data suggest that these two transcripts are independently regulated by YvrH as a positive regulator, but YvrH binding sites in the upstream of *sunA* and *sunT* have not been found [Serizawa et al. 2005], the negative regulator of these genes, Rok binds to the promoter region of *sunA* only [Albano et al. 2005], and these transcripts have functional relation of sublancin 168. Therefore, the five gene cluster, *sunATyolIJK*, may comprise an operon including the internal operon, *sunTyolIJK*.

(A)

	Average number of conserved species
KOP	**13.9**
Gene pairs except KOP	**7.3**

(B)

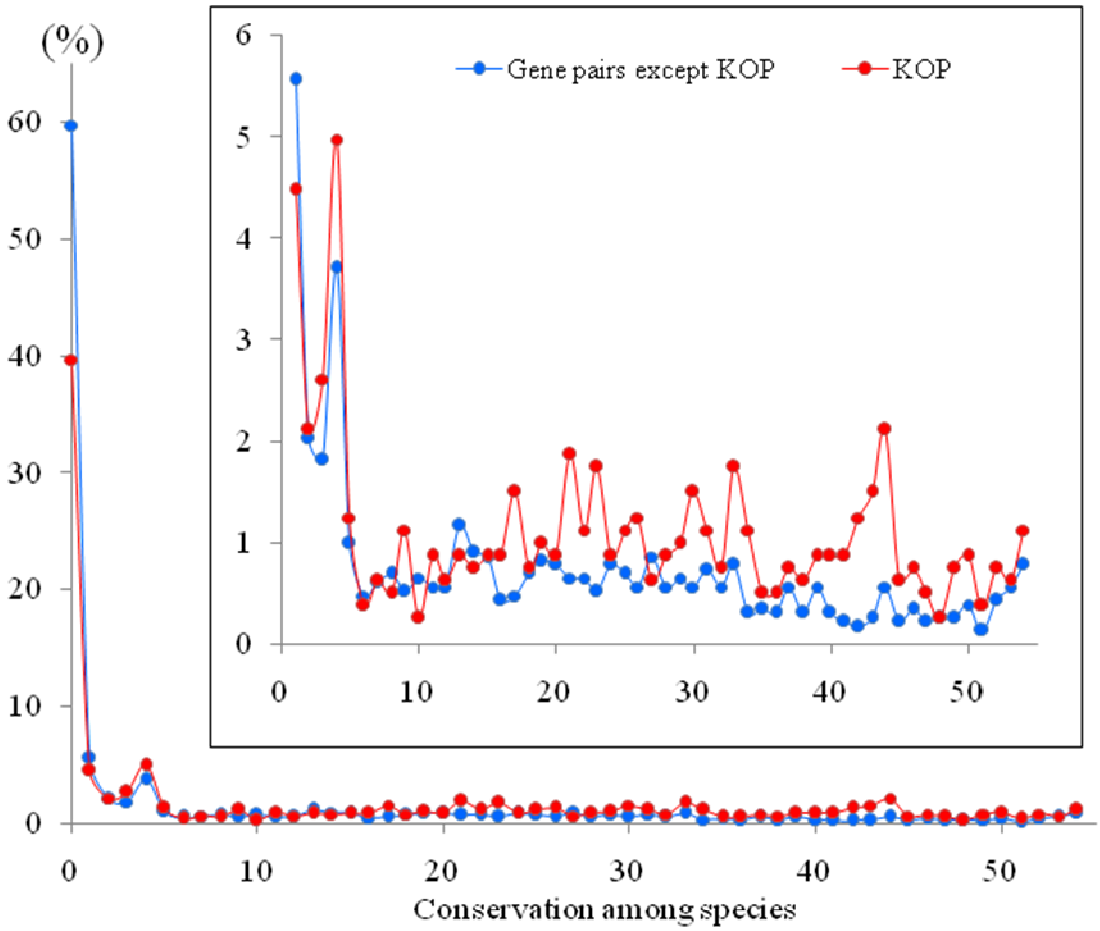

Figure 13. Conservation of consecutive gene pairs in the same directions among Gram-positive bacteria. (A) Average number of conserved species of orthologous gene pairs. (B) Conservation ratio of *B. subtilis* gene pairs between *B. subtilis* and 54 Gram-positive bacteria.

KOP refers to a known operon pair.

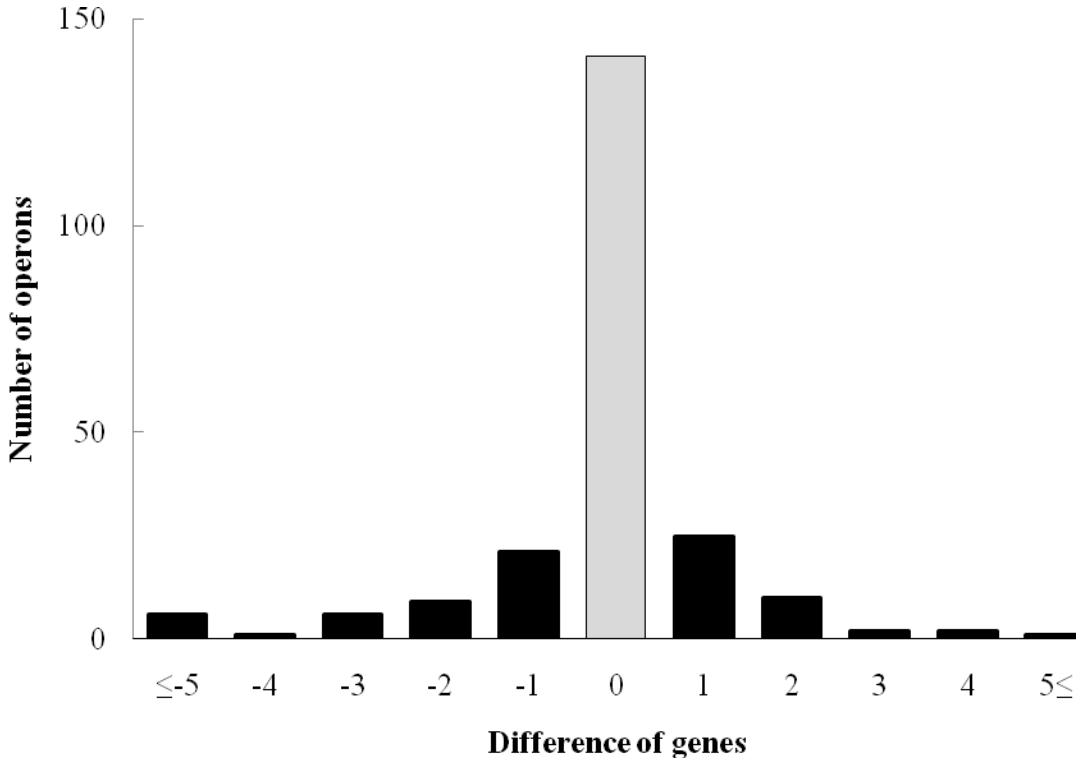

Figure 14. Comparing operons predicted in the integrated approach with known *B. subtilis* operons, which start with the same promoters as the operons. 62.9% of the known operons matched the predicted operons (i.e., 141 predicted operons in the 224 known *B. subtilis* operons); when I included operons lacking or gaining one gene of known operons, this figure rose to 83.5%. The x-axis indicates difference in gene number between predicted operons and known *B. subtilis* operons, and the y-axis indicates the number of predicted operons.

4 Operon Prediction by Support Vector Machine

4.1 Introduction

SVM is a computer based algorithm that belongs to a family of generalized linear classifiers and is closely related to neural networks. This is a set of related supervised learning methods used for classification and regression. When there exist many decision boundaries separating the samples into two classes, SVMs find the one that achieves the maximum margin between them using statistical learning theory.

Recently, this supervised learning technique has been utilized to perform in multiple area of biological analysis. For instance, SVMs examined the gene expression profile from ovarian cancer tissues, normal ovarian tissues and other normal tissues [Furey et al. 2000]. As a result of the computational analysis, they were able to classify tissue and cell types based on data sets, and discovered and confirmed to be cancer cells some that were mistakenly labeled. Brown et al. [2000] demonstrated that SVMs could accurately classify genes into some functional categories based on microarray expression profiles and identify the functions of unannotated yeast genes. Another analysis showed exact translation initiation sites in order to identify protein sequences from nucleotide sequences by SVM with an appropriate kernel function [Zien et al. 2000]. In this way, SVMs have been recently used in bioinformatics as classifiers for biological objects: proteins, DNA sequences, microarray expression profiles and mass spectra [Noble 2004].

In this study, I employed SVM as a classification tool for *B. subtilis* operon prediction using features based on a large amount of data: (i) intergenic distance data, (ii) expression data, (iii) comparative genomic data, and (iv) *B. subtilis* specific functional data. I also examine discrimination capacity of boundaries between intra operons and inter operons by combination of the four features of (i) - (iv).

4.2 Data

4.2.1 Microarray Data

For Pearson correlation coefficients, I used 98 time-series gene expression data in *B. subtilis* 168 grown in 13 different time-series growth conditions: anaerobic growth; competent medium; cold-shock experiments; DSM medium; DGG medium; glucose-limited medium; heat-shock

experiment; LB medium; minimum-glucose medium; sodium-shock conditions; phosphate-starvation medium; and SOS stress experiments. I also used 394 gene expression data of *B. subtilis* σ-factor and TF deletion mutants which were *sigB, D, E, F, G, H, K, L, M, W, X, abrB, acoR, ahrC, alsR, arsR, azlB, codY, comA, cspB, deoR, exuR, fnr, fruR, glcT, gntR, gutR, hpr, hutP, kdgR, lacR, lexA, mntR, msmR, mtrB, pksA, rbsR, spo0J, ybbH, ysiA, yvaN, yvrH, yybA, yybE, yydK, araR, ccpC, citT, comK, ctsR, fur, glnR, hrcA, iolR, lmrA, perR, purR, resD, rocR, sinR, treR, xylR, zur, ccpA, degU, gerE, phoP, spo0A, spoIIID* and *spoVT* deletion mutant. Furthermore, I used 312 public gene expression data from Gene Expression Omnibus (GEO) in NCBI which were GPL188, GPL1353, GPL2760, GPL3645, GPL3655, GPL3665, GPL3668, GPL3671, GPL3949, GPL3950, GPL4694 and GPL6031 in GEO accession numbers [GEO].

4.2.2 Genomic Data

The genome sequence of *B. subtilis* and the annotation files were obtained from the NCBI ftp site [NCBI FTP]. The leading and lagging strands were scanned based on whether they were transcribed in the same directions or in different directions. The 4225 genes in the linear chromosome were binned into 3000 same-strand pairs and 1224 opposite-strand pairs.

4.2.3 Comparative Genomic Data

Comparative genomic data was obtained from OperonDB [Ermolaeva et al. 2001]. I used two types of data sets; one data set contained probability that a gene pair is located in the same operon and the other data set was the number of other genomes that have the same pair of genes located in the same directon.

4.2.4 Functional Data

Functional data was obtained from DBTBS. I used 32 functional classifications for sorting 4,224 gene pairs into three groups: same functional pairs, different functional pairs and unknown pairs.

4.3 Methods

4.3.1 Microarray Data Normalization

Details of all protocols are described in chapter **3.2.2**.

4.3.2 Calculation of Pearson correlation coefficients of neighboring genes

Pearson correlation coefficients of neighboring genes were calculated using a 4225 (genes) × 804 (samples) matrix.

4.3.3 Intergenic Distance Calculation

Intergenic distance in base pairs between the genes in every gene pair ($gene_I$ - $gene_{II}$) was calculated as $distance_{I-II} = gene_{II}\_start - gene_I\_end - 1$. Negative intergenic distance implies an overlap between the translated regions of the two genes.

4.3.4 Supervised Classification

4.3.4.1 Training Set: Positive and Negative Classes

The training set consists of 805 known operon pairs (KOPs) based on northern bolts, primer extension analyses and nuclease protection assays from DBTBS and BSORF databases. The set of gene pairs that comprise the negative class was created using the genes composing known monocistronic operons and their immediately upstream on downstream genes. These gene pairs are referred to as known boundary pairs (KBPs) and a set of 272 KBPs constitutes the negative class.

4.3.4.2 Model Training and Selection

Binary SVM classifiers were trained for operon prediction using five different features: Pearson correlation coefficient between neighboring genes having the same direction, intergenic distance, two comparative genomic data, and gene function data. Intergenic distance is measured in base pairs, whereas the Pearson correlation coefficient is bound between -1 and 1. Due to the large difference in the range of these features, scaling was performed by discretizing the intergenic distances into six bins corresponding to $d \leq 0$, $0 < d \leq 20$, $20 < d \leq 50$, $50 < d \leq 100$, $100 < d \leq 300$ and $d > 300$ bp. Therefore, I used vectors in ith gene pair with 10 components called features:

$$\mathbf{x}_i = (r^i, d_1^i, d_2^i, d_3^i, d_4^i, d_5^i, d_6^i, P_{operon}^i, P_{directon}^i, f^i).$$

Here r is the Pearson correlation coefficient of neighboring genes, d_n (n = 1, 2, …, 6) is binary data made of six bins based on the intergenic distances, P_{operon} is the probability that a gene pair is

located in the same operon based on OperonDB, $P_{directon}$ is the probability that a gene pair is located in the same directon based on OperonDB and f is binary data based on the DBTBS gene function. The discrimination rule established during training can result in over-fitting whereby the classifier cannot accurately discriminate test/unseen data. Leave-one-out cross-validation was therefore performed to estimate the performance of the model in classifying an independent dataset that was not used for training.

4.3.4.3 Support Vector Machines

The SVM algorithm is the kernel learning algorithm [Vapnik 1998]. It performs robust pattern recognition using well-established concepts in optimization theory. In the 10-dimensional feature space, I limited two-class classification problems and identified the two classes with the class (+) for OPs and (–) for BPs. A training set of a number of patterns (S):

$$S = \{(x_1, y_1), (x_2, y_2), \ldots (x_n, y_n)\}, y_k \in \{-1,+1\},$$

is given. The training patterns are used to build a decision function $f(x)$, that is a scalar function of an input pattern x. New patterns are classified according to the sign of the decision function:

$f(x) > 0 \Rightarrow x \in$ class (+)

$f(x) < 0 \Rightarrow x \in$ class (–)

$f(x) = 0$, decision boundary.

Decision functions are simple weighted sums of the training patterns plus a bias. In this notation:

$$f(x) = (w \cdot x) + b ,$$

where w is the weight vector and b is a bias value and both are determined by running a learning procedure on a training set S, and $(w \cdot x)$ indicates an inner product of w by x.

In this study, I used SVM^{light}, an implementation of SVM in C used for model training and evaluation [Joachims 1999]. Radial basis function (RBF) on non-linear mapping, was used for classification. The RBF transforms the data using the nonlinear function:

$$K(x_1, x_2) = \exp(-\gamma \| x_1 - x_2 \|^2) ,$$

where γ determines RBF width. For the radial kernel function, the parameters γ (–g) and the cost function (–c) were selected using the leave-one-out model selection (looms) procedure [Lee and Lin 2000]; I used 128.0 as the constant for soft margin, and 1.024 as the constant for RBF. The algorithm calculates the leave-one-out error rates for a range of parameters and outputs the one with the minimum error rate.

4.3.4.4 Leave-one-out Approach

Leave-one-out cross-validation is an iterative approach where each gene pair in the training set of '*n*' gene pairs is left out in one iteration. The model is trained with (*n - 1*) gene pairs and used to classify the nth gene pair. In each iteration, the true class of the pair (whether it is a KOP or NBP) is compared with the predicted class. The performance of the model is then evaluated using different metrics.

4.4 Results and Discussion

4.4.1 The features for SVM

The intergenic distance between a pair of adjacent genes is a powerful feature for operon prediction [Salgado et al., 2000; Moreno-Hagelsieb and Collado-Vides, 2002]. I used 805 KOP and 272 KBP, and showed distributions of KOP and KBP with respect to intergenic distance (Fig. 16). 28.2 % of KOPs have an intergenic distance less than 0 bp; i.e., the end of one gene overlaps the start of the next, and 88.9 % of KOPs have a distance of less than 100 bp. In the range, KOPs have two peaks around intergenic distances of 0 and 15 bp. In contrast, 1.1 % of KBPs overlap between the neighboring genes. Genes belonging to the same operon tend to exhibit small intergenic distance having two sharp peaks. On the other hand, intergenic distance distribution of genes that do not belong to the same operon is represented by a gentle curve having the maximum between 100 and 200 bp (Fig. 16). Observing the intergenic distance distribution of all pairs of *B. subtilis* genes, it can be said that this distribution is probably represented by the combined shape.

In this research, I used original features: the Pearson correlation coefficient and identity of function by DBTBS functional classification between adjacent genes with the same direction. The average value of the correlation coefficients of KOPs was about twice as much as that of KBPs (Table 7). Moreover, the number of gene pairs with the same function was about twice as much as the number with different function in KOPs, whereas 85 % of KBPs (in case of function known genes) were of different functions (Table 7). The feature of correlation is typically used in many operon predictions [Charaniya et al. 2007; de Hoon et al. 2004], and I could detect the bias of correlation between KOPs and KBPs in this research using huge microarray data and therefore this feature is useful for operon-boundary discrimination by SVM. KOPs were likely to be composed of same function pairs based on DBTBS functional classification; the same functional

pairs were about twice as much as the different functional pairs in KOPs, and KBPs had a strong tendency to be of different functional pairs. Some studies used functional similarity for operon prediction [Price 2005], but I used more detailed functional classification (32 classifications) than those used in other studies, so this functional classification could be a useful feature.

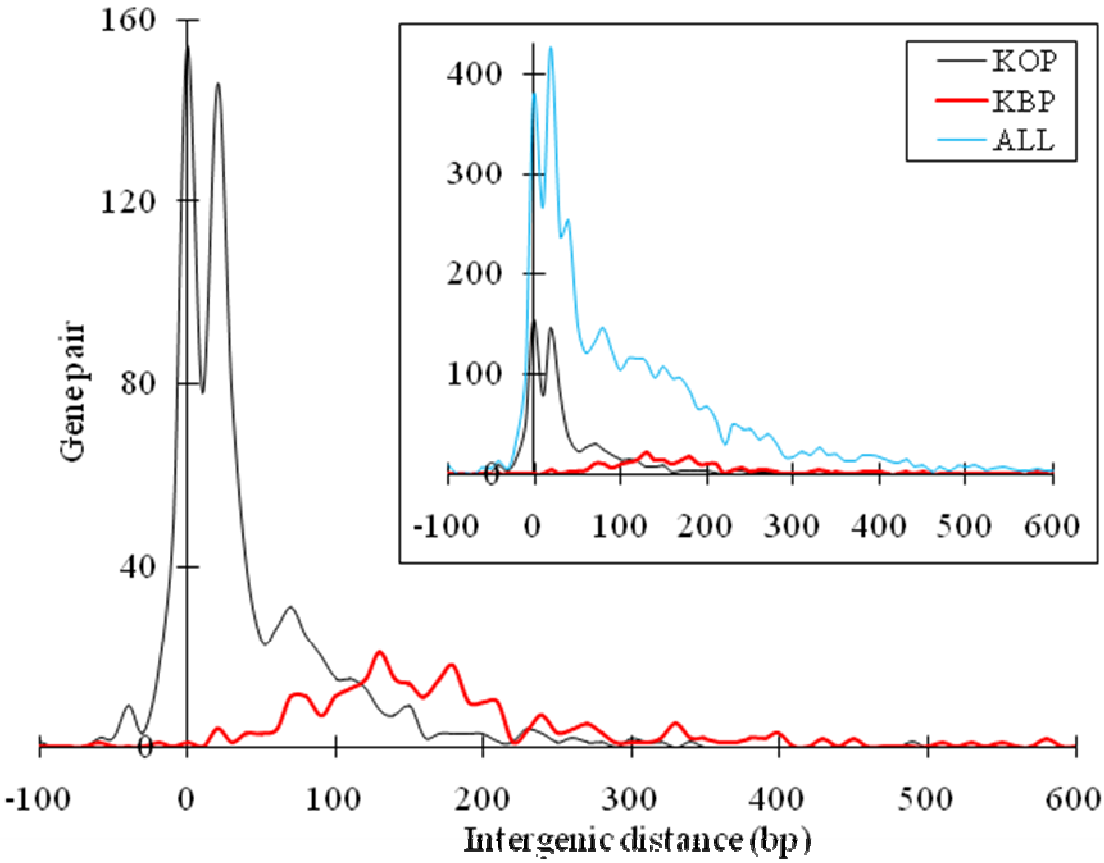

Figure 16. Frequency intergenic distance distributions of KOP (known operon pairs), KBP (known boundary pairs) and ALL (all *B. subtilis* gene pairs).

Table 7. Average value of Pearson correlation coefficients and DBTBS functional composition of KOP and KBP.

	Correlation	Function	
		same	different
KOP	0.66	334	170
KBP	0.32	11	62

4.4.2 Kernel functions for SVM

For the SVM classifier, I applied two kernel functions: linear kernel and radial basic function (RBF) kernel. In the linear classification by SVM, I perfectly detected KOPs in the range of intergenic distance below 100 bp and KBPs in the range of them with 100 bp or more, but I could not detect KOPs and KBPs in the other range at all (Fig.17). The performance of the linear classifier was strongly affected by feature of the intergenic distances. I made 6 bins on the basis of intergenic distance and used the features for the classifier, and then 88.9 % of KOPs belong to the four bins of intergenic distances with 100 bp or less and 80.5 % of KBPs reversely belong to the two bins of them with 100 bp or more. Compared with the other features, the distribution of KOPs and KBPs was biased across 100 bp on the feature of intergenic distance, and thus this feature had strong effect for the performance of classifier (Table 8).

Next, I discriminated OPs from BPs using non-linear SVM with RBF kernel. This kernel function played the role of the dot product in feature spaces. I separated 3,000 gene pairs into OP and BP on 10 dimensional feature hyperplane, and I could detect perfectly KOPs in the range of intergenic distance below 50 bp, 98.1 % of KOPs in the four bins of intergenic distances with 100 bp or less, and 50.1 % of KOPs in the two bins of these with 100 bp or more. Meanwhile, I detected 58.6 % of KBPs in the four bins of intergenic distances with 100 bp or less, and 93.9 % of KBPs in the two bins of these with 100 bp or more. Using only intergenic distance as the feature for SVM, the identification of KOPs and KBPs by the linear SVM and the RBF kernel SVM was similar, but the detection of KOPs and KBPs by non-linear SVM were considerably improved by RBF kernel function when more features were applied as input vectors. In the range of non-detecting KOPs and KBPs by linear classification, the non-linear SVM classifier especially identified KOPs and KBPs on account of effect of the features except intergenic distance (Table 8), and reversely the detection ratio of KOPs decreased by 1.95 % and the ratio of KBPs decreased at 6.07 % in the range of full-detecting KOPs and KBPs by linear classification. With allowance for soft margin in the RBF kernel SVM, I slightly failed the detections of known gene pairs which were identified by linear SVM [Tarca et al. 2007]. This may be because SVM is sensitive to noise, so the non-linear classifier was affected by noise in accordance with increasing features, but the detection ratio of total KOPs and KBPs certainly improved using non-linear classifier compared to liner classifier and thus this method could be more reliable than linear SVM.

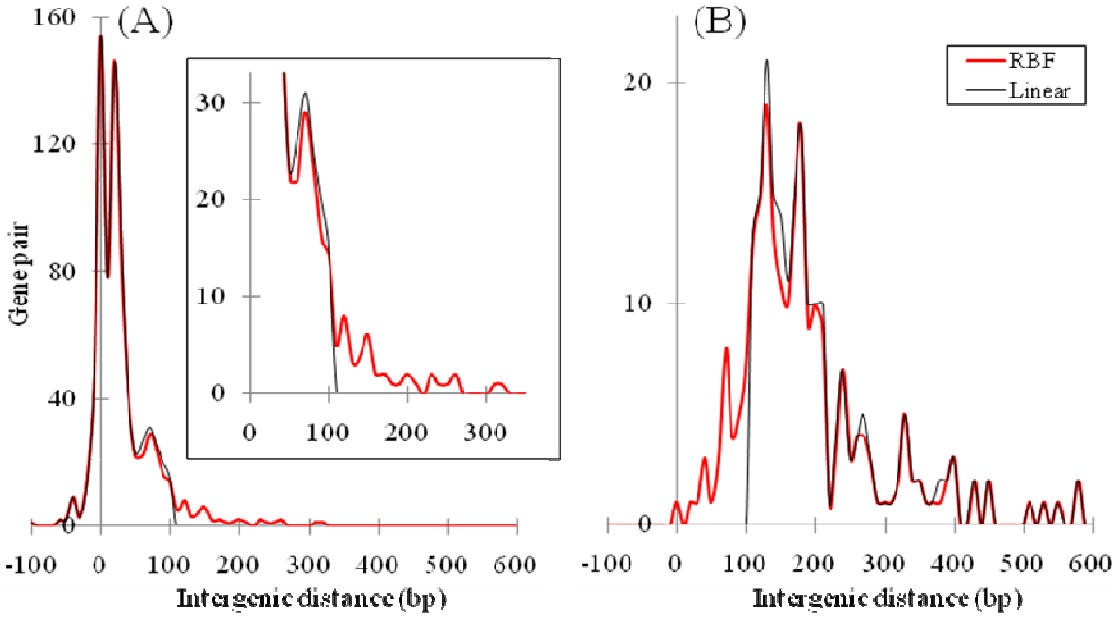

Figure 17. Comparison between linear classification and non-linear classification using radial basic function. (A) Distribution of identified KOPs. (B) Distribution of identified KBPs.

bp represents base pair.

Table 8. Comparison of different classifiers based on intergenic distances.

		$d \leq 0$	$0 < d \leq 20$	$20 < d \leq 50$	$50 < d \leq 100$	$100 < d \leq 300$	$d > 300$

d represents intergenic distance using number of base pairs.

[a] linear refers to linear SVM classification.

[b] RBF refers to non-linear SVM classification using radial basic function kernel.

4.4.3 Binary classification by non-linear SVM

For separating OPs and BPs in the *B. subtilis* genome, I used SVMs to binary classification of the gene pairs using the five types of features. I combined these features and estimated the contribution for separating OPs and BPs by detection ratios of KOPs and KBPs (Fig. 18). In the case of using all features, I identified 92.9% of KOPs and 86.4% of KBPs.

When only intergenic distance was used for classification of training set, 89.2% of KOPs and 78.7% of KBPs were classified as OPs and BPs respectively. Meanwhile, 92.1% of KOPs and 46.3% of KBPs were classified as OPs and BPs respectively, when only Pearson correlation coefficient was used for classification, and when the other features except intergenic distance and Pearson correlation coefficient were used for classification, every gene pairs were sorted into OPs. These results show that each feature significantly affects classification of gene pairs into OPs, but intergenic distance is likely to have critical contribution of detecting BPs. Moreover, I used SVM classifier with combination of these features, and then over 75% of KBPs were classified as BPs, when intergenic distance and Pearson correlation coefficient or the other features are combined, but I identified only 56.6% of KOPs in the case of using the features except intergenic distance. Therefore, the feature of intergenic distance critically influences the SVM classifier for separating OPs and BPs from the *B. subtilis* gene pairs as the results of previous studies showed that intergenic distance can be effectively used for operon prediction in other prokaryotes [Westover et al., 2005; Moreno-Hagelsieb and Collado-Vides, 2002]. The other features secondarily affect the classification and improve the detection ratios of the KOPs and KBPs with combination of the four types of features.

Using the classification results by SVM, one or more OPs that were composed of consecutive genes on the same strand were regarded as polycistronic operons. I detected 2,669 genes composing 806 operons, which include known operons, from the complete *B. subtilis* genome. This method separates all genes into two groups, so I identified precise structures of operons from many consecutive genes with the high classification accuracy (Fig. 19). For model organisms like *B. subtilis*, SVM could be useful classifier for detecting whole operons on genomes because we can use many kinds of information about the organisms.

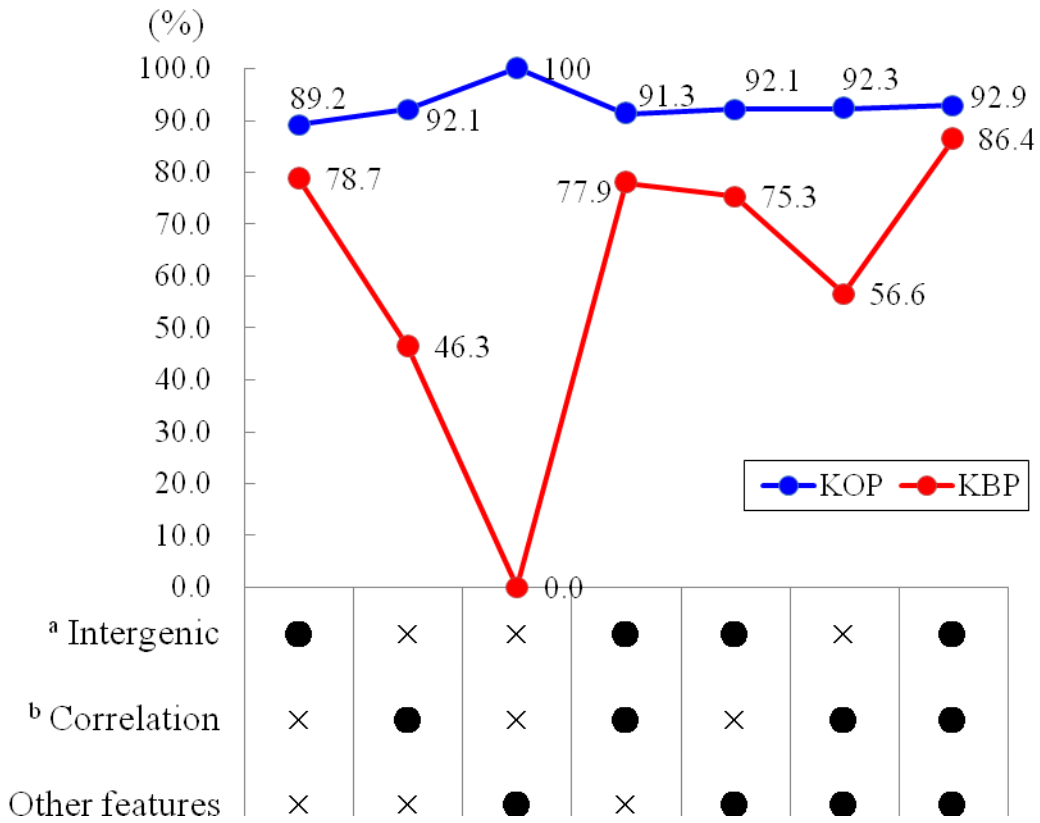

Figure 18. Effect of particular features for non-linear SVM classification.

[a] Intergenic refers to a feature of intergenic distance (bp).

[b] Correlation refers to a feature of Pearson correlation coefficient.

● represents used feature and × represents non-used feature in the SVM classification.

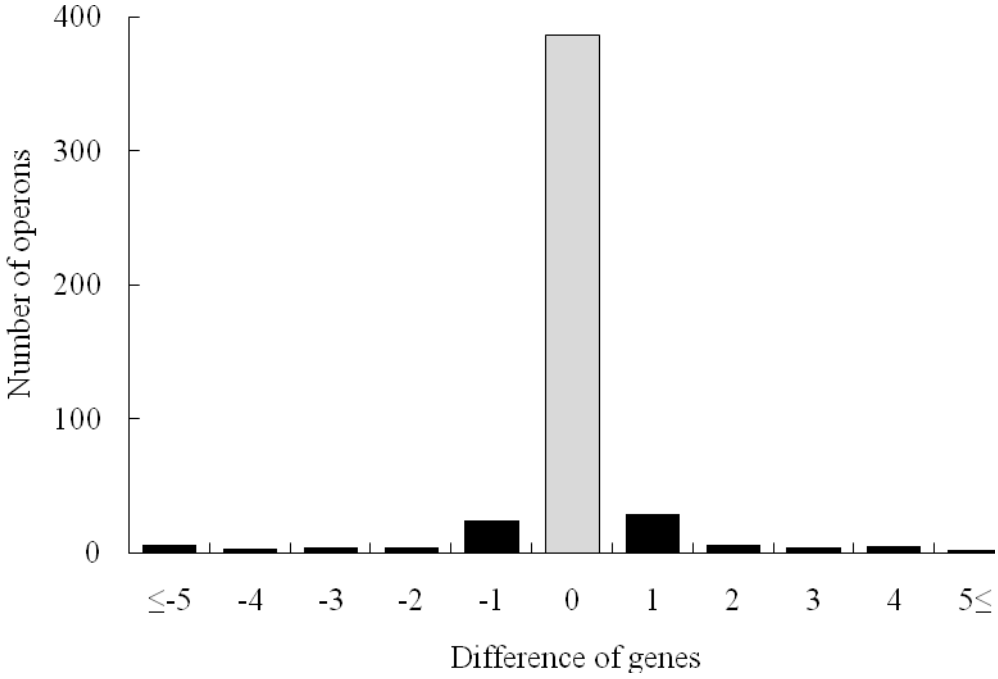

Figure 19. Comparing operons predicted by non-linear SVM with known *B. subtilis* operons, which start with the same promoters as the operons. 81.6% of the known operons matched the predicted operons (i.e., 387 predicted operons in the 474 known *B. subtilis* operons); when I included operons lacking or gaining one gene of known operons, this figure rose to 92.8%. The x-axis indicates difference in gene number between predicted operons and known *B. subtilis* operons, and the y-axis indicates the number of predicted operons.

4.4.4 Comparison of other operon predictions

Several studies have predicted operons in *B. subtilis* whole genome and have used some methods including SVM. Regardless of supervised learning, almost all approaches used intergenic distance as a feature in operon prediction and thus each approach was characterized by other features and various algorithms. In the previous operon prediction method using SVM, Zhang et al. [2006] applied the KEGG pathway data, the conserved gene data among 98 bacteria, the phylogenic profiles and the domain interaction data by Pfam database. I cannot simply compare my result to their result, since they used 310 KOPs and 121 KBPs as training set for SVM which was fewer than half compared to my training set, but my detection of KOPs improved by 2.9 % from their result (Table 9). Some studies applied Bayesian classifier using gene expression data [de Hoon et al. 2004] and GO similarity score [Dam et al. 2007] as characteristic features. Most methods have also been used successfully for operon prediction incorporating different approaches but there was no method detecting operons completely (Table 9). Compared with other predictions of *B. subtilis* operons, my approach is the best for identification of KOPs. This result suggests that the combination of the features used in proposed method is appropriate for detecting operon pairs. On the other hand, my approach is inferior in identification of KBPs to a couple of other results (Table 9). This is because the features for my approach were operonic information and thus I may need to add specific and precise information of boundary pairs as the feature for SVM for raising the precision of detection of boundary pairs.

Table 9. Comparison of operon predictions with previous methods.

	This research	de Hoon (2004)	Price (2005)	Zhang (2006)	DAM (2007)

BP (%)	86.4	87.9	88.0	86.0	90.8

5 Conclusion

Various technical innovations for investigating the structures of micro-organisms and their workings have recently brought us many kinds of information about micro-organisms including bacteria, and we can use this information all over the world with the rapid progress of communication engineering. A part of these data, however, contain noise caused by the properties of materials and investigating techniques, and thus technologies for extracting the proper biological information are demanded. In bacterial operon analyses, many studies have demonstrated various approaches for identifying operon structures on genomes using clues about the relationship between genes: intergenic distances [Salgado et al. 2000], transcription control signals [Huerta and Collado-Vides 2003], phylogenetic information based on comparative genomic analyses [Bergman et al. 2007], functional relatedness of two adjacent genes [Westover et al. 2005], and global changes in gene expression [Sabatti et al. 2002]. Moreover, some studies have adopted integration of these clues and efficiently identified operons on genomes [de Hoon et al. 2004; Dam et al. 2007]. In this study, I tried to demonstrate two methods for identifying operons in *B. subtilis* by integration of these clues.

The first approach is an integrated approach for identification of TUs based on statistical and PWM algorithmic methods, and comparative genomic analysis. The integrated approach used two types of cDNA microarray data: time series expression profiles using the cells grown in different growth conditions, and gene expression data of σ-factor and TF deletion mutants, and σ-factor and TF binding sequential data, and thus I efficiently detected genes composing TUs regulated by each σ-factor and TF in the *B. subtilis* genome, and thus I predicted gene regulation networks. In addition, using the comparative genomic analysis in the integrated method, I was able to detect operons candidates and identified σ-factor and TFs regulating operons including internal operons. Moreover, this integrated analysis demands no training data, and thus this method is useful for organisms for which the amount of accumulated data about operons is small.

In the other approach, I used an SVM-based supervised classification approach to predict operon structure for the whole genome. After the determination of the complete genome sequence of the *B. subtilis* genome, various information about this organism, for example, expression data, sequence data, and functional data has rapidly increased, and thus a vast amount of information is available to detect most operonic gene pairs in the genome. As a result, SVM is a very effective approach for identifying operon boundaries in *B. subtilis*, i.e. this method is very useful for operon

prediction for organisms for which huge amount of operonic data is available.

Comparing polycistronic operons detected by the integrated approach with those detected by SVM, 85.8% of genes composing polycistronic operons detected by the integrated approach were identified as the genes detected by SVM (Fig. 20). Figure 20 also shows that 2,811 genes compose polycistronic operons on the *B. subtilis* genome, so one third of genes in the *B. subtilis* genome are monocistronic operons, considering the gene number of *B. subtilis* (Fig. 20). Among overlapping operons identified by both of the approaches, the number of operons identified by the SVM approach (SVM operons) encompassing operons identified by the integrated approach (INT operons) is more than twice the number of INT operons encompassing SVM operons (Table 10). SVM is a binary classification method and every gene pair in the genome is divided into two groups: operon pair and boundary pair, and thus I could detect longer operons than the integrated approach (Table 10). The integrated approach is based on statistical analyses for TFs and gene expression data, and thus this method is useful for detailed structures in operons regulated by each TF, and then I could find internal operons in the overlap regions. In these regions, I also identified 116 operons with identical composition by both analyses and detected 64 new operons structures in these operons (Table 10, Table 11). There are a few reports about the function of the genes in newly identified operons, but the operons including known functional genes are mostly found to be composed of the same or similar functional genes: *uxaCyjmB, gltBA, spoIIIAHIIIAGIIIAFIIIAEIIIADIIIACIIIABIIIAA, yqxAspoIIPgpr, yusKL* and *uppglyA*, and thus these newly identified operons would be reliable (Table 10).

Therefore, both of these methods should respectively contribute to studies of predicting operons in the bacterial genomes and which method to apply to a particular case depends on the availability of data type and data quantity. Furthermore, combining these results could reliably predict operon structures on the genomes.

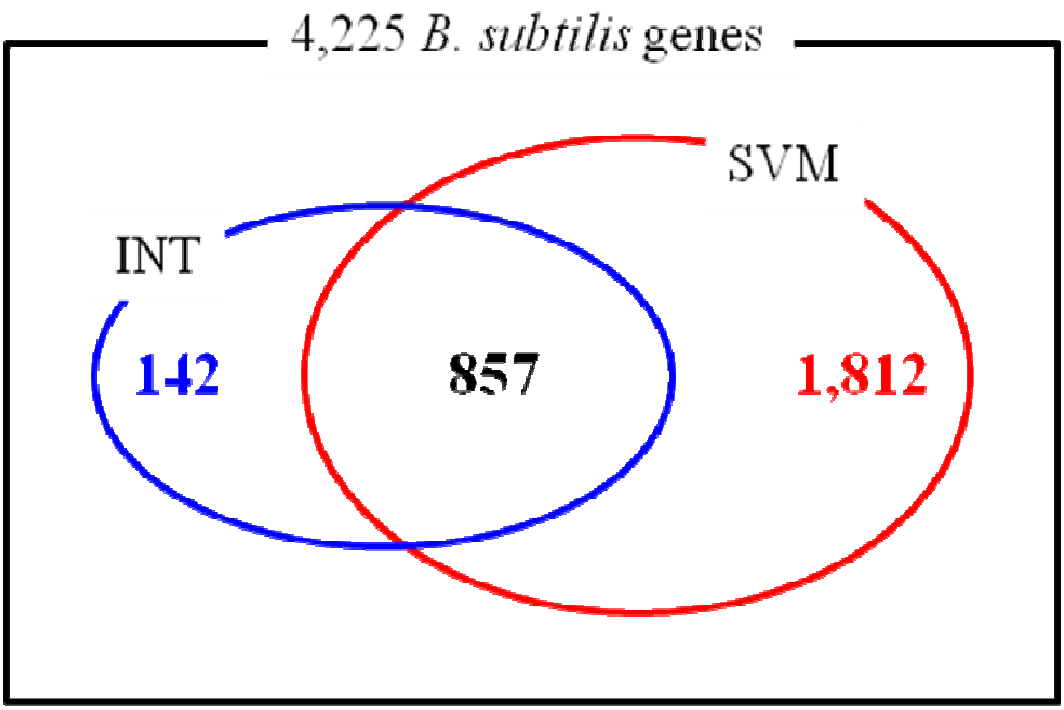

Figure 20. Formation of genes belonging to polycistronic operons identified by the integrated and SVM approaches.

Each figure refers to number of genes identified by these approaches.

INT refers to the integrated approach and SVM refers to support vector machine approach.

Table 10. Comparing gene composition in operons identified by the integrated and SVM approaches in overlap regions on the *B. subtilis* genome.

Gene composition of operons identified by INT and SVM in the overlap regions	Sum
SVM operon encompassing INT operon 	98
INT operon encompassing SVM operon 	44
A part of genes overlapping between both operons 	56
Identical composition 	116

INT operon refers to operon identified by the integrated approach and SVM operon refers to operon identified by support vector machine approach.

Appendix

Appendix A. Operon map on the *B. subtilis* genome identified by the integrated analysis
Purple thin arrows refer to known *B. subtilis* operon structures (DBTBS).

Appendix B. Functional conformation of *B. subtilis* operons identified by the integrated analysis.
[a] CDF is an abbreviation of compound degree of functions.
[b] These numbers indicated gene functions by DBTBS at respective positions in the operon.

Appendix C. Classification of operon pairs and boundary pairs by support vector machine analysis.
Yellow columns indicate operon pairs and blue columns indicate boundary pairs.
