Abstract—The popularity of super repositories such as Maven Central and the CRAN is a testament to software reuse activities in both open-source and commercial projects alike. However, several studies have highlighted the risks and dangers brought about by application developers keeping dependencies on outdated library versions. Intelligent mining of super repositories could reveal hidden trends within the corresponding software ecosystem and thereby provide valuable insights for such dependency-related decisions. In this paper, we propose the Software Universe Graph (SUG) Model as a structured abstraction of the evolution of software systems and their library dependencies over time. To demonstrate the SUG’s usefulness, we conduct an empirical study using 6,374 Maven artifacts and over 6,509 CRAN packages mined from their real-world ecosystems. Visualizations of the SUG model such as ‘library coexistence pairings’ and ‘dependents diffusion’ uncover popularity, adoption and diffusion patterns within each software ecosystem. Results show the Maven ecosystem as having a more conservative approach to dependency updating than the CRAN ecosystem.

I. INTRODUCTION

Reusing software by depending on libraries is now commonplace in both open source and commercial settings alike [1], [2]. Software libraries come with the promise of being able to reuse quality implementations, thus preventing ‘*reinventions of the wheel*’ and speeding up development. Examples of popular reuse libraries are the SPRING [3] web framework and the APACHE COMMONS [4] collection of utility functions. Contributing to the popularity of these and other libraries has certainly been the ease through which they can be accessed nowadays from ecosystems formed by a collection of *super repositories* such as Maven Central [5], R’s CRAN [6], Sourceforge [7] and GitHub [8].

With new libraries and newer versions of existing libraries continuously being released, managing a system’s library dependencies is a concern on its own. Improper dependency management can be fatal to any software project [9]. As outlined in related studies [10], [11], [12], dependency management includes making cost-benefit decisions related to keeping or updating dependencies on outdated libraries. Additionally, a recent study [13] reported that 87.5% of developers do not update their dependencies, a result that

complements other studies that show updating library APIs is slow and lagging [14], [15], [16], [17]. This study found that such update decisions are not only influenced by whether or not security vulnerabilities have been patched and important features have been improved, but also by the amount of work required to accommodate changes in the API of a newer library version. Recently, there also has been other work that studies dependency issues at the ecosystem level [18], [19], [20].

Meta-data recorded within these ecosystems can provide system maintainers valuable “wisdom-of-the-crowd” insights into these dependency-related questions. We introduce the Software Universe Graph (SUG) as a means to model the realities of popularity, adoption and diffusion within a software ecosystem. Popularity refers to the usage of a library over time. Adoption refers to systems introducing a new library dependency. Diffusion, inspired by use-diffusion [21], is a measure of the spread of library versions over dependent systems. The abstract nature of our SUG enables generalizing and hence comparing these aspects across different types of super repositories.

To evaluate the SUG model, we report on a large-scale empirical study in which we construct SUGs for a large collection of Maven and CRAN super repositories. Our goal is to: (1) construct real-world SUG models to show its practical application and (2) demonstrate its usefulness in library dependency management through several case studies. Our key contributions are:

- We introduce the fully formalized SUG model for representing super repositories in a generic manner, which lends itself to being mined for insights about popularity, adoption and diffusion.
- We define several metrics related to popularity, adoption and diffusion—all in terms of formal operations on a SUG model. We also introduce several SUG-based visualizations.
- In a large-scale study, we build SUG models for the very different realities of the Maven and of the CRAN super repositories. We demonstrate that our visualizations intuitively provide valuable insights for dependency

management. The study results empirically depict Maven users as reluctant to update to newer library releases, with older library releases deemed ‘usable’ by the crowd. CRAN users are more disciplined in this regard.

II. BACKGROUND

Studying library usage in terms of absolute popularity is not a new concept. Holmes et al. appeal to popularity as the main indicator to identify libraries of interest [22]. Eisenberg et al. improve navigation through a library’s structure using the popularity of its elements to scale their depiction [23]. De Roover et al. explored library popularity in terms of source-level usage patterns [24]. Popularity over time has received less attention. Mileva et al. study popularity over time to identify the most commonly used library versions [25]. Follow-up work applies the theory of diffusion to identify and predict version usage trends [26]. Similar to our diffusion work, Bloemen et al. [27] explored the diffusion of Gentoo packages. Using the economic bass model, they modeled the diffusion of gentoo packages over time. Teyton et al. use ‘library migration graphs’ to identify candidate library migrations [11].

Instead of a single-dimensional analysis of popular library usage, we present an extensively formalized SUG model with popularity and variety metrics and additional complementary diffusion and coexistence plot visualizations. This provides for a much richer understanding of significant phenomena in the evolution of library dependencies.

III. SOFTWARE UNIVERSE MODELING

This paper is concerned with intelligent mining of a large collection of software repositories within an ecosystem, defined as *super* repositories. More specifically, we present an abstract model to understand and compare adoption, diffusion and popularity within its particular *universe*. We conjecture that useful information such as popularity is indicative of a library reliability, which is measured by significant usage within the ecosystem.

A. Software Universe Graph

We present the *Software Universe Graph* (SUG) as a structural abstraction of a super repository. Figure 1 will serve as an illustration of the different relationships within the graph. Let $G = (N, E)$ for a graph G . N is a set of nodes, with each node representing a software unit. We consider both any system version, such as *SymmetricDs* version 3.6.3 (*SymmetricDs*_{3.6.3}) or a library version *Junit* version 4.11 (*Junit*_{4.11}) as software unit nodes. For any SUG, the edges E are composed of E_{use} and E_{update} . E_{use} is a set of *use-relations* and E_{update} is a set of *update-relations*. We first present E_{use} in Definition 1 and 2. E_{update} is then introduced in Definition 3.

Definition 1: An edge $u \rightarrow v \in E_{use}$ means that u uses v . The defined functions of E_{use} are:

$$Used(u) \equiv \{v | u \rightarrow v\} \quad (1)$$

$$UsedBy(u) \equiv \{v | v \rightarrow u\} \quad (2)$$

Use-relations can be extracted from either the source code or configuration files. As depicted in Figure 1, node $a1$ uses node $x1$. Also node $x1$ is used by nodes $a1$, $q1$ and $q2$. Parallel edges for node pairs are not allowed. In this paper, we focus on popular software units that are connected by many use-relation edges.

Definition 2: For a given node u , popularity is the number of incoming use-relation edges and is defined as:

$$popularity(u) \equiv |UsedBy(u)| \quad (3)$$

For instance in Figure 1, for node $x1$, $popularity(x1) = |UsedBy(x1)| = |\{a1, q1, q2\}| = 3$. As an extension, the popularity of any pair of nodes (u and v) is defined by the number of common nodes connected by an incoming edge. Formally,

$$popularity(u, v) \equiv |UsedBy(u) \cap UsedBy(v)| \quad (4)$$

We define u and v as being *coexistence pairs* if $popularity(u, v) \geq 1$. Take from Figure 1, $popularity(x1, a1) = |\{UsedBy(x1) \cap UsedBy(a1)\}| = |\{a1, q1, q2\} \cap \{q1\}| = |\{q1\}| = 1$. Therefore in the Figure, $x1$ and $q1$ are coexistence pairs.

Definition 3: We represent an update-relation from node a to b using $a \Rightarrow b$, meaning that newer update b had been released from node a and is defined as:

$$a \Rightarrow b \in E_{update} \quad (5)$$

Update-relations refers to when a succeeding release of a software unit is made available. Figure 1 shows that node $q1$ is first updated to node $q2$. Later on, node $q2$ is updated to the latest node $q3$. Hence, $q1 \Rightarrow q2 \Rightarrow q3$. We find that every node in the SUG should be denoted by three attributes: $\langle name, release, time \rangle$. For a node u , we then define:

- **u.name** Name is the string representation identifier of a software unit. We introduce the name axiom: For nodes u and v , if $u \Rightarrow v$, then $u.name = v.name$ holds.
- **u.release**. Release refers the specific assigned change reference for a software unit. For nodes u and v , if $u \Rightarrow v$ then v is the immediate successor of u . Note that the versioning pattern may vary from project to project.
- **u.time**. Time refers to the time-stamp at which node u was released. For nodes u and v of $u \Rightarrow v$, $u.time < v.time$.

An example of the attributes can be shown with the *JUNIT* library. These attributes belong to the most recent release¹ (i.e., $\langle name = "junit", version = "4.11", time = "2012-11-14" \rangle$). We define a set of nodes weakly connected by update-relations as a *lineage*. We are interested in all releases within a lineage.

Definition 4: Lineage of a related set of nodes is determined through transitive update-relations. This is defined as:

¹<http://mvnrepository.com/artifact/junit/junit/4.11>: accessed 2017-04-01

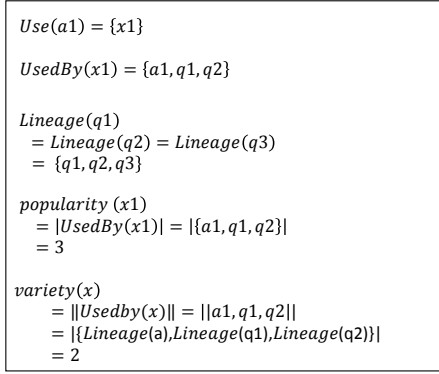

Fig. 1. A Conceptual Example of the Software Universe Graph with formalized definitions and notations.

$$Lineage(u) \equiv \{v | v \xrightarrow{\pm} u \vee u \xrightarrow{\pm} v \vee u = v\} \quad (6)$$

where $a \xrightarrow{\pm} b$ is the transitive closure on any update-relation $a \Rightarrow b$.

The name axiom proves that all names in a lineage are the same. A lineage of nodes is depicted in Figure 1, where $Lineage(q1) = Lineage(q2) = Lineage(q3) = \{q1, q2, q3\}$. The lineage function enables more dynamic operations. To differentiate between lineages, we now introduce an additional operator.

Definition 5: We use the $\| S \|$ operator to represent the number of different lineage in a set of nodes in S .

$$\| S \| \equiv |\{Lineage(u) | u \in S\}| \quad (7)$$

Looking back at the example in Figure 1, suppose $S = \{a1, a2, x1\}$. Hence, $\| S \| = |\{Lineage(a1), Lineage(a2), Lineage(x1)\}| = |\{\{a1, a2\}, \{x1\}\}| = 2$. Complex queries on our SUG model based on lineages are now possible. The previously defined *popularity* function alone is insufficient in reflecting the spread or diffusion of a software unit across the software universe. We introduce a *variety* function that allows us to measure diffusion.

Definition 6: Variety represents the number of different lineages that use a software unit.

$$variety(u) \equiv \| UsedBy(u) \| \quad (8)$$

In Figure 1 we observe that node $x1$ is used by node related to $Lineage(a1)$ and $Lineage(q1)$. Hence, variety is 2. Formally, $variety(x1) = \| \{a1, q1, q2\} \| = |\{Lineage(a1), Lineage(q1), Lineage(q2)\}| = 2$.

Definition 7: The SUG has temporal properties. This describes the simultaneity or ordering in reference to time. Let SUG $G = (N, E)$ be at time t . At time $t' > t$, we observe an extension of G , such that:

$$G' = (N \cup \Delta N, E \cup \Delta E) \quad (9)$$

where $\Delta E \cap (N \times N) = \emptyset$.

Fig. 2. Temporal property of the SUG

Figure 2 illustrates the temporal properties of the SUG. Here, it is observed that G' is composed of G augmented with newly added node $a3$ and its corresponding $a3 \rightarrow x2$ and $a2 \Rightarrow a3$ relations. A SUG grows monotonically over time with only additions. Here we consider that modification or deletion changes on the SUG do not occur.

Definition 8: A timed SUG specifies the state of the SUG at any point in time. So for a SUG $G = (N, E)$, we represent a timed SUG G_t at time t as a sub-graph of G . Formally,

$$G_t \equiv (N_t, E_t) \quad (10)$$

where $N_t = \{u | u \in N, u.time \leq t\}$ and $E_t = \{e | e \in E \wedge e \in N_t\}$.

We are now able to describe the temporal properties of popularity. We introduce $Popularity_t(u)$ for a node u at time t . This provides the popularity of u for G_t ².

B. Query Operations on the SUG Model

We utilize the SUG model to query and retrieve useful information from the software ecosystem. We now introduce *Coexistence Pairing* and *Diffusion Plots* as examples of the visualization of popularity. Our rational is that popular usage of a software unit is evident by successful adoption and diffusion over its predecessors. It is important to note that results do not indicate concrete evidence of library compatibility, instead

²We define that $Popularity_t(u) = 0$ if $t < u.time$

Fig. 3. Illustrative example of the coexistence pairing. Let Figure 3(a), shows a typical SUG G with respective lineages annotated. Figure 3(b) is the L-SUG G' . Finally in Figure 3(c), the popularity is determined. In this case the coexistence popularity (a, b) is 2.

popularity suggests some recommended usages based on the ‘wisdom of the crowd’.

Coexistence pairing examine and explores occurrences of specific combinations between software components. We empirically visualize these coexistence pairs, deemed to be compatible by the ‘crowd’. The coexistence popularity of two nodes (i.e., $popularity(u, v)$) is used to establish a pairing between the nodes. Alternatively, non coexistence pairs (i.e., $popularity(u, v) = 0$) suggest combinations that are possible but not seen yet. To aggregate nodes by lineage, we introduce a reduced SUG called Lineage SUG (L-SUG).

Definition 9: A Lineage SUG is used to merge all related nodes into a single node. We define a Lineage SUG (L-SUG) $G' = (N', E')$ of an SUG $G = (N, E = E_{use} \cup E_{update})$ where:

$$N' = \{Lineage(u) | u \in N\} \quad (11)$$

and

$$E' = \{Lineage(u) \rightarrow Lineage(v) | u, v \in N \wedge u \rightarrow v \in E_{use}\} \quad (12)$$

In the L-SUG, all nodes belonging to the same lineage are merged with all use-relations mapped onto the merged node. All update-relations are discarded. Almost all defined functions for the SUG like popularity, should theoretically apply on the L-SUG³. An example of the L-SUG is explained in Figure 3. Figure 3(a) shows a typical SUG G with respective lineages annotated. Figure 3(b) depicts the lineage SUG G' . In Figure 3(c), the L-SUG popularity of L-SUG nodes a and b is calculated. We now introduce the three different types of coexistence pairing operations as follows:

- 1) **L-SUG Lineage Pairs.** We use the *popularity* of two L-SUG nodes. Further exploration of the lineage pairs would lead to release pairs of these lineages.
- 2) **SUG Release Pairs.** Once interested lineage pairs are identified, maintainers next decide on popular release combinations. To this end, we use *popularity* of two nodes on the SUG to establish coexistence release pairs.
- 3) **L-SUG Lineage Coexistence Rank.** The coexistence rank returns popularity pairs relative to a specific L-SUG

³An exception would be L-SUG variety, which is a lineage within an lineage. We consider this to be out of scope for this study.

Fig. 4. Example of the coexistence operation. For the L-SUG Pt , for a node a , the coexistence rank allows to determine popularity in relation to node a . In this example node s has the highest coexistence rank.

node. Formally, for a node u on a set of L-SUG U , we compute all values of $popularity(u, v)$ for $v \in U$ where $popularity(u, v) \geq 1$. We refer to them as the *coexistence rank*. For example in Figure 4, consider L-SUG node a . The coexistence rank returns 5 results, with node s having the highest coexistence rank of 2. Later in Section IV-C, we demonstrate how the coexistence rank may uncover intuitive insights.

As an extension on our work of Library Dependency Plots (LDP) [28], we introduce Diffusion Plots. For any software unit, DPs enable plotting and tracking both popularity and variety at any given point in time t such that $popularity_t(u)$ and $variety_t(u)$ for a node u . The DPs provide a temporal means to evaluate popularity and the adoptive behavior of a software unit within its universe. We introduce the two main attributes of the DP:

- **Popularity and Variety Plots.** DPs plot both the $popularity_t$ and corresponding $variety_t$ on a SUG. We use the plots to understand the adoption and diffusion at both the lineage and release level.
- **Diffusion Curve Types.** The DPs allow us to perceive patterns of popularity for a specific release belonging to a lineage. Additionally, the DPs provide insights on the adoption and diffusion within that universe.

In Figure 5, we show an example DP of the MOCKITO-CORE lineage from the Maven super repository. For illustration purposes –and to simplify the curve– this DP only shows two releases. Note the crossing of lines, which is described as the *superseding point* where MOCKITO-CORE_{1.8.5} succeeds MOCKITO-CORE_{1.8.4} in both $popularity_t$ and $variety_t$. Section IV-D details the DP visualizations.

IV. EMPIRICAL STUDY

A. Case Study of Maven and CRAN Ecosystems

Our aim of the empirical study is to demonstrate: (1) practical application of our formalized SUG model when applied to real-world data and (2) usefulness by providing insights and comparisons between two different ecosystems. In detail, we demonstrate how our model operations and visualizations support describing real-world data. All tools, scripts, data and results are freely available on request.

Fig. 5. A simple example of the diffusion plot for the Maven MOCKITO-CORE lineage release 1.8.4 and 1.8.5

TABLE I
CONSTRUCTION OF THE SUG USING ATTRIBUTES STORED FOR MAVEN
JAR BINARIES AND CRAN ZIP WINDOWS PACKAGES.

	Maven	CRAN
File type	POM.xml	DESCRIPTION
E_{use}	<dependency>	Depends:
E_{update}	<version>	Version:
$x.name$	<groupId>.<artifactId>	Package:
$x.release$	<version>	Version:
$x.time$	time-stamp of jar binary	indicated build time

To demonstrate the practicality of the SUG, we construct and apply the SUG model and its operations to a large collection of Maven Central [5] and CRAN [6] super repositories. We then perform model operations on both the Maven and CRAN SUGs to demonstrate the usefulness of our models. By selecting different examples, we show different insights on adoption, diffusion and popularity within each universe. The Maven Central super repository is a major super repository that hosts many JVM project artefacts from the Java programming language ecosystem. Note that most projects in this repository are open-source Java, Scala or Clojure libraries (referred to as artefacts). R [29] is a free software environment for statistical computing and graphics. The Comprehensive R Archive Network (CRAN) belongs to an R ecosystem that hosts sources, binaries and packages related to the R environment. For the experiment, we only targeted contributed packages under windows⁴ (from R version 1.7 to 3.1).

B. SUG Construction and Analysis

Table I shows the different attributes collected from meta-files, that we used to construct the SUGs. We constructed each SUG by extracting (i) use-relations, (ii) update-relations and (iii) software attributes such as the name, release and time properties of each software in the ecosystem. Specifically, we employed a typical extraction method of dependency information using meta-files [11], [30], [31], [32]. For the Maven libraries, we use the Project Object Model file (i.e., POM.xml) that describes the project's configuration meta-data—including its compile-time dependencies⁵, while each

TABLE II
SUG STATISTICS FOR MAVEN LIBRARIES AND CRAN PACKAGES

	Maven	CRAN
Time Period	2005-11-03 to 2013-11-24	2003-08-29 to 2014-08-22
# of nodes	188,951	93,184
# of lineages	6,374	6,506
Reuse	5,146	1,517

TABLE III
SUMMARY STATISTICS FOR L-SUG POPULARITY

	Maven	CRAN
Min	1	1
1st Quartile	2	4
Median	6	8
Mean	38.8	64.62
3rd Quartile	20	22
Max	10160	26460

CRAN package stores its dependency information in a file called 'DESCRIPTION'⁶.

Table II presents a summary of data mined for the experiment. For our SUGs, our tools were able to mine and generate 188,951 Maven and 93,184 CRAN nodes from each super repository, spanning across 9-11 years. Note that independent software units (i.e., without use-relation edges) were not included in SUGs. For the CRAN universe, we also include both available and archived packages⁷. The SUGs were built from the dates shown in Table II. To understand the reuse within each universe, we measure how many lineages are being used internally. For every node u in SUG U :

$$reuse = \parallel \bigcup_{u \in U} UsedBy(u) \parallel \quad (13)$$

Table II details each SUG. The results suggest that the CRAN universe reuse is comprised of a much smaller subset of reuse libraries (i.e., 1,518 lineages). In contrast, for Maven there is an indication of more reuse within the universe (i.e., 5,146 lineages are used by 6,374 other lineages). We find this result not so surprising as most Maven artifacts comprise of either libraries or frameworks that may depend on multiple libraries.

⁴<http://cran.r-project.org/bin/windows/contrib/>

⁵Refer to <http://maven.apache.org/pom.html> for the data structure

⁶<https://goo.gl/H1S1vJ>

⁷<http://cran.r-project.org/web/packages/> reports 5,833 at time of experiment

To determine popularity of a lineage, we apply the popularity function on a L-SUG. Hence, from the Maven and CRAN SUGs, we derive their respective L-SUGs with a lineage by lineage use relation. The statistical summary of this L-SUG popularity distribution for both Maven and CRAN is presented in Table III. Surprisingly, we observe that except for the median and the 3rd quartile, both distributions of the Maven and CRAN universes seem similar. We had expected that since CRAN exhibited lower reuse (shown in Table II), it would be more likely to generate higher popularity counts. For Maven, the testing library JUNIT was the most popular, while dependency on the R package release was found to be the most popular in CRAN packages.

C. Coexistence Pairs using Heat Maps

We utilize a heat map matrix to visualize coexistence pairs. We define the intensity as a normalized frequency count of popular pairs. For a given set of nodes I , for pairs $x, y \in I$ intensity is:

$$intensity(x, y, I) = \frac{popularity(x, y)}{\max_{\substack{i, j \in I \\ i \neq j}} (popularity(i, j))} \quad (14)$$

where $x, y \in I$ and max returns the most frequent counts of pairing. The *Intensity* function allows for normalized intensity shading of tiles from a scale of 0 to 1 (darker indicates higher popularity) by returning the most frequent pair count.

Using the L-SUG popularity, we utilize the heat map and the intensity function to plot popular pair frequency counts. Figure 6 illustrates examples of these lineage pairings. Figure 6(a) depicts the pairing of eight selected Maven Apache Commons [4] artifacts built for Java. From the matrix, it is observed that the most popular pairing is between COMMONS-LOGGING, a log helper and COMMONS-COLLECTIONS, a library used for handling data structures. In Figure 6(b), we observe two cases of non-coexistence. Figure 6(b) shows the top 10 most popular dependent packages⁸ in CRAN. Notice that pairs (TCLTK, MATRIX) and (TCLTK, MVTNORM) lack coexistence. We speculate but cannot confirm that common functionality of handling complex matrices manipulation and GUI could be a reason. The pairing of (GRAPHICS, STATS) as the most frequent package combination is typical. This is because it is known as the ‘free software environment for statistical computing and graphics’ [29]. In summary, the results provide at a glance hints of popular pairings at the lineage level.

From the lineage pairing (L-SUG), popularity on the SUG is used to determine release pairs between two lineages. A heat map matrix with the intensity is used for this visualization. Figures 7(a), 7(b), 7(c) and 7(d) depict the release pair plots between Maven’s ASM [33], COMMONS-IO [34], COMMONS-LOGGING [35] and COMMONS-LANG [36]. Figures 7(e) and 7(f) show release pair plots between CRAN’s MASS [37], MVTNORM [38] and LATTICE. Different to the L-SUG lineage pairs, the popularity is annotated at each pairing point.

⁸excluding the R dependency

(a) Lineage pairings of eight Apache commons artifacts

(b) Top 10 popular CRAN package dependents (excluding R). Notice that pairs TCLTK, MATRIX and TCLTK, MVTNORM lack coexistence.

Fig. 6. Example of Coexistence Lineage Pairing

Additionally, the release pair plots include the popularity of a specific version x and any other software unit ‘outside’ $Lineage(y)$. It is plotted at the end of the x and y axis of the release pair plot. Formally, for each node n in U :

$$outside(x, y) = \sum_{\substack{n \in U \\ Lineage(n) \neq Lineage(x) \\ Lineage(n) \neq Lineage(y)}} popularity(x, n) \quad (15)$$

The *outside* pairs gauge relative popularity of alternative combinations. For instance, in Figure 7(b), the popularity of pairing Maven COMMONS-IO_{1.4} and ASM_{3.2} (popularity of 579) is greater than both ‘outside’ COMMONS-IO_{1.4} (popularity of 210) and ASM_{3.2} (popularity of 75). This classifies

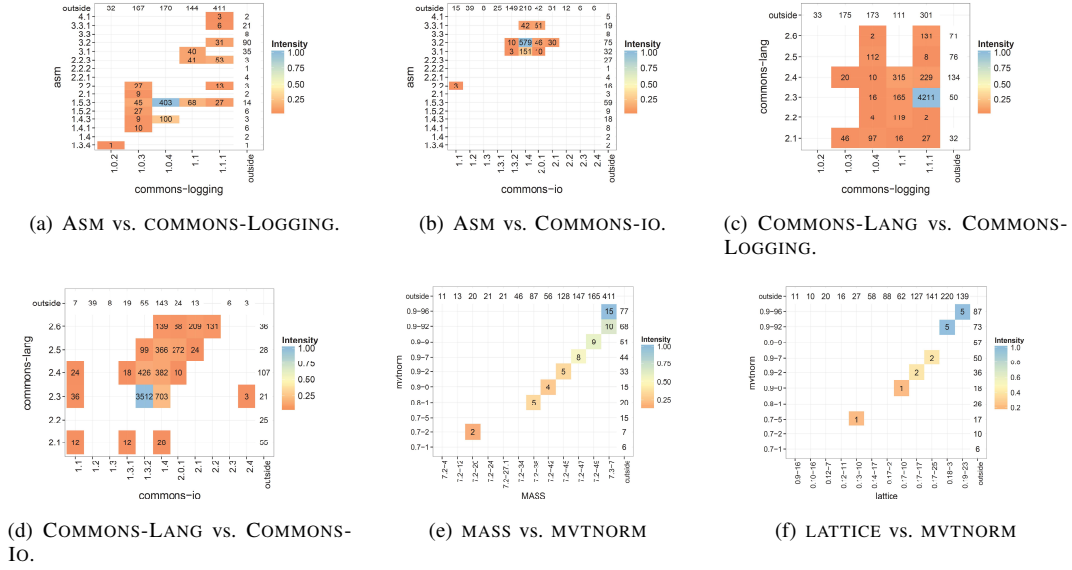

Fig. 7. Example of Coexistence Mapping for both Maven Artifacts (a,b,c,d) and CRAN Packages (e,f). Note the different co-evolving patterns.

Fig. 8. Conceptual example of release pairs patterns, provide hints of popular pairings with older releases or if co-evolution (diagonal pattern) occurs.

this pairing as very popular. On the other hand in Figure 7(e), CRAN’s $MASS_{7.3-7}$ and $MVTNORM_{0.9-96}$ (popularity of 15) lower than the ‘outside’ $MASS_{7.3-7}$ (popularity of 411) indicate that the (MASS, MVTNORM) pair combination is not the most popular possible pairing combination.

Co-evolution patterns assist with interpretation of the evolution between the two lineages. As depicted in Figure 8, co-evolving patterns such as the *diagonal* co-evolving pattern can be identified from the heat map matrix. As shown in Figure 8, pairings with older releases can be easily distinguished. Figure 7(a) highlights COMMONS-LOGGING_{1.0.3} and COMMONS-LOGGING_{1.1.1} as popular pairings for ASM releases, forming an almost vertical pattern. While in Figure 7(b), there seems to be no apparent co-evolving pattern, with the ‘crowd’ settling on the ASM_{3.2} and COMMONS-IO_{1.4} pairing. Patterns from Figure 7(c) indicate that older releases of COMMONS-LANG have popular pairings with even newer COMMONS-LOGGING releases. Figure 7(d) displays a more diagonal co-evolving pattern between COMMONS-LANG and COMMONS-IO.

Back to Figures 7(a), 7(b), 7(c) and 7(d) the intensity indicates that the most popular Maven ‘crowd choices’ are not necessarily the latest releases of their respective lineages. Maven maintainers seem conservative with older versions. Quite in contrast to the Maven pairings, CRAN packages depict a more distinguished diagonal pattern of co-evolution. This is illustrated in Figures 7(e) and 7(f). There are some inconsistencies such as non-coexistence and overlapping pairs. Take for instance, the ($MASS_{7.3-7}$, $MVTNORM_{0.9-92}$) and ($MASS_{7.3-7}$, $MVTNORM_{0.9-96}$) pairings. This is due to the same version ($MASS_{7.3-7}$) being released over two consecutive R releases. Also different to Maven, the most popular ‘crowd choices’ are the latest releases of their respective lineage. We conjecture that regular updates by maintainers to comply with the latest R release build check⁹ may contribute to why CRAN packages are so well maintained. Also as outlined by Mens [39], since only a single version is allowed per release of R, maintainers must update to the compatible version or risk their package being removed in the next release. Regular updates for R packages may account for why the most popular releases are the most frequent release pairs.

Finally from the Maven super repository, we provide an example of an L-SUG *coexistence rank*. We perform the *coexist* function on an L-SUG of Maven, thus allowing a lineage as a node input. The operation returns lineages that at some point in time had a coexistence pairing. The Maven lineage artefact COMMONS-DBCP, a relational database connector [40] was used as an illustrative example. Using the Maven L-SUG, the *coexistence rank* returned 513 results. Table IV pertains to the top 10 results. Note that the list comprises of many non-database, general-purpose libraries such as JUNIT and LOG4J. For a more useful result, the use of

⁹the latest build is accessible at <http://cran.rstudio.com/>

TABLE IV
TOP 10 FILTERED FREQUENT COUNTS OF *coexistence rank* FOR
LINEAGE COMMONS-DBCP

lineage	<i>coexistence rank</i>
junit	37

TABLE V
TOP 10 FREQUENT COUNTS OF *coexistence rank* FOR
LINEAGE COMMONS-DBCP EXCLUDING POPULAR LINEAGES.

lineage	<i>coexistence rank</i>
mysql-connector-java	11
postgresql	10
c3p0	8
spring-test	7
cglib	6
aspectjweaver	4
bsh	4
geronimo-spec-jms	4
proxool	4
spring-web	4

L-SUG popularity thresholds (shown in Table III) can be used to remove the more general purpose lineages, creating a more domain-specific result. We removed lineages that were above the 3rd quartile popularity threshold. The filtered results are provided in Table V.

Compared to Table IV, the results in Table V provide more database-specific entries such as MYSQL-CONNECTOR-JAVA¹⁰, POSTGRESQL¹¹, C3P0¹² and PROXOOL¹³. The filtered results are not entirely database-specific such as SPRING-WEB¹⁴. As an extension, we can further explore lineage pairing of the domain-specific results in Table V. Figure 9 depicts this result. Popular pairings of both POSTGRESL and MYSQL-CONNECTOR-JAVA suggest that in regards to COMMONS-DBCP, the postgresql and mysql databases are popular among the Maven ‘crowd’. The non-coexistence of MYSQL-CONNECTOR-JAVA and ASPECTJWEAVER¹⁵ suggests that maintainers who depend on the ASPECTJWEAVER library should pay special attention to ‘the wisdom of the crowd’, as for one reason or another the crowd avoids its coexistence with the MYSQL-CONNECTOR-JAVA library. Additional operations of filtering and heat map lineage pairing are examples of how users can use any combination of SUG operations.

Fig. 9. Top COMMONS-DBCP filtered coexistence ranked lineage pairs

D. Diffusion Plots

A key element lacking in the coexistence pairing visualizations are the SUG *temporal* properties. Diffusion Plots (DPs) are used to this end, so that adoption and diffusion of a lineage is seen at any point in time. For any lineage, we describe both *popularity_t* and *variety_t*. For popularity, we plot the number of software units using a particular release of the lineage. Conversely in the variety plot, we track the number of lineages that use a specific release. Popularity is characterized as a curve that depicts important visual features, such as the steepness, when the curve halts and when the curve is *superseded* by a successive release curve. Figure 10 provides examples of DPs for both Maven and CRAN.

Figures 10(a) and 10(b) depict DPs for two lineages within the Maven Repository. COMMONS-LANG is a helper utility library, notably assisting with Java string manipulation methods, basic numerical methods, object reflection, concurrency, creation and serialization. COMMONS-LOGGING is a java logger helper library. As seen in Figure 10(a), COMMONS-LANG_{2.4} (dark green) it is overall the most popular although older release. It is deemed as ‘stable’ by the ‘crowd’. The steepness of the curve can be interpreted as the adoption trend. For instance in the *variety_t* plot of Figure 10(b), we observe that COMMONS-LOGGING_{1.0.4} has the most variety at any point in time. However, closely looking at its curve (light green), popularity has probably peaked with the curve being almost horizontal. COMMONS-LOGGING_{1.1.1} (pink), however, adopts a more diagonal curve, hinting future adoptions could follow this trend. Note that the predecessor COMMONS-LANG_{2.4} (dark green) in Figure 10(a) is still adopted beyond the COMMONS-LANG_{2.3} obsolete point, making it more successful. Significant difference between *popularity_t* and the corresponding *variety_t* reveals lineages with abnormally high releases depending on this specific lineage release. For instance, in Figure 10(a), on the y-axis depicts *popularity_t* > 150 while *variety_t* > 40. Such variances could be misleading, so care should be taken in its interpretation.

The DPs of the CRAN universe exhibit a very different adoption and diffusion behavior. Figures 10(c) and 10(d) show the DPs of both MASS and MVTNORM lineages. The

¹⁰MYSQL-CONNECTOR-JAVA is a MySQL database java connector

¹¹POSTGRESQL is a PostgreSQL Driver JDBC4

¹²C3P0 is a JDBC Connection pooling / Statement caching library

¹³PROXOOL is a Java connection pool.

¹⁴SPRING-WEB is the web component of the spring framework

¹⁵ASPECTJWEAVER AspectJ weaver introduces aspect-oriented advices

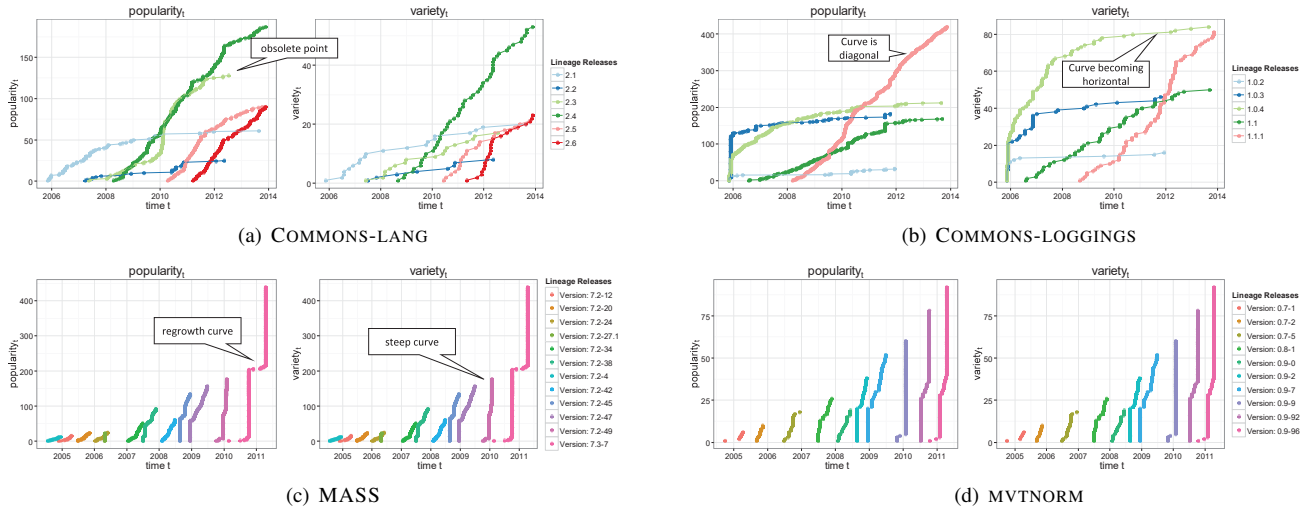

Fig. 10. Dependents Diffusion Plots for selected Maven and CRAN lineages. The left hand depicts the $popularity_t$ while the right shows the $variety_t$ for their respective releases.

Mass package supports functions and datasets for Venables and Ripley’s MASS while the MVTNORM package computes multivariate normal and t probabilities, quantiles, random deviates and densities. These are depicted in Figure 10(c) and 10(d), with regular superseding of the previous release. Previous release curves never overlap but grow incrementally over time. Note that the most popular library versions are the latest releases. Differences in corresponding $popularity_t$ and $variety_t$ values are minimal. This is consistent with the fact that only a single lineage release is permitted per R release. The steepness of the rate of adoption is almost vertical, meaning migration to newer releases is almost instantaneous, while making previous releases obsolete. In Figure 10(c), the $Mass_{7.3-7}$ curve follows an abnormal *regrowth type* shape possibly caused by migration to a newer R release. In summary, DPs offer a visualization of adoption and diffusion patterns for a lineage. This has shown to be particularly useful in the case of the Maven universe, where adoption is slow and older releases are still popular. Particularly, results in Figure 10(a) coincide with Figure 7(c), where the older releases of COMMONS-LANG are still preferred over newer versions. Superseding points may provide hints on when it is safe to update. Additionally as shown, care must be taken when interpreting variance in $popularity_t$ and $variety_t$.

V. DISCUSSION

SUG Model Considerations. The SUG model enables a standardized comparison of use-relations across diverse structured universes of software repositories within the ecosystem. The model allows for uncovering adoption, diffusion and popularity within a super repository universe, that is useful for assessing dependency management issues for developers. In this study, we only looked at two different ecosystems, however, we would like to investigate more ecosystems such as the ‘C programming language’ libraries universe. As the rise of cross-language (or platform) systems emerge, potential future

research avenues could be the adaptation from a different universe and how system applications deal with cross-universe interaction. The use of an abstract model has its drawbacks, such as disregarding more complex concepts such as package ‘containment’ and ‘transitive’ relationships. At this stage we only consider the basic elements of software usage to measure popularity. As we study more systems, we will consider modeling additional concepts common to all universes as extensions to the model. A concern in the SUG construction was the assignment of the R_{use} and R_{up} edges in relation to the name attribute of the node. Threats specific to the Maven and CRAN repositories, such as changed domains or lineage from more multiple nodes exist. Nevertheless, conceptually the SUG model was successfully applied to each universe. For future improvements of accuracy the model can expand beyond the name attribute for lineage classifications. We plan to incorporate more sophisticated techniques and tools used in ‘code clone’ such as code clone detection [41], [42] and ‘origin’ analysis [43], [44] to determine common lineage. Recently, Ishio et al. presented a promising technique to find software provenance using its Software Bertillonnage [45].

There exist many definitions of software variability and dependency relationships. In Software Product Line Engineering (SPL), terms such as ‘product’ variability have been used extensively [46], [47], [48]. In the code clones field, Kim et al. [49] coined clone ‘genealogies’ to track variability between software of similar origins. To coincide with the abstract nature of the SUG and avoid preconceptions, we decided on the term ‘lineage’ to describe variability between software releases. In addition, systems and libraries are not explicitly distinguished. Graph cyclic based approaches such as page ranking, reference counting, and component ranking are common for measuring popularity on graph based models [11],[50]. Our SUG model does not employ any of these approaches as it is designed to rely on the dependency chains

to measure immediate dependency characteristics directly.

Model Operations. As stated in our background, related studies have all reported maintainer’s concerns with API breakages and incompatibilities of existing dependencies over time. The results of this study revealed that the coexistence mapping provides interesting visual patterns. Assuming that usage implies stability, we can identify combinations of lineages deemed safe by the ‘crowd’. The coexistence operations on the SUG demonstrate more ‘intuitive’ aspects of the model, although domain-specific filtering may be required. Another complex but useful operation that was not presented in this paper is the tracing of systems that have abandoned a dependency. This could be future work. The Diffusion Plots (DPs) provide for a more temporal analysis of popularity and diffusion. Consistent with the SUG temporal properties, the restriction of adding nodes results in incremental adoption curves. The accumulating growth provides for a comparison of previous releases. Overall the DPs describe different adoption behaviors within the universe. Our qualitative visualizations indicate that maintainers of CRAN packages are more inclined to update to the latest version of their dependencies. The conservative nature of Maven artifact maintainers on the other hand, further justifies the potential usefulness of the SUG. Its model querying visualizations should assist maintainers to gain intuitive insights and understand the opportunities for updating components. We envision that an integration of both the coexistence and DP temporal properties into a single visualization would be beneficial. This is seen as future work.

In practice, basing update decisions solely on popularity is not practical as there are often many other factors to consider. Therefore for a complete toolkit, popularity should be complementary to the many existing code and API compatibility checking tools. Ultimately, the maintainer’s personal preference may override all suggestions of the crowd. Our aim is to provide additional insights to maintainers who have to make a timely choice.

Threats to Validity. The main internal threat to validity is the real-world assessment of the usefulness of our model. We believe that we are currently only at the conceptual stage of the research. We have been working closely with system integration industrial partners to develop and test our visualizations. We have received positive feedback regarding the modeling and particularly concerning coexistence. Another threat is that the results that we show may not generalize to all types of systems. We understand that in reality the repository data can be modified such as when changing domain locations, thus threatening the temporal property. Our investigations have proven, however, that most SUGs hold the temporal property.

An external threat is that our datasets only include information about dependencies that are explicitly stated in project configuration files, such as the Maven POM and R Description files. It does not take into account reuse such as copy-and-paste and clone-and-own. Although gauging dependencies by the configuration file only provides for a sample of the actual reuse, we believe this is sufficient to give an impression of trends within each universe. We understand

that our data and analysis are dependent on the tools and analysis techniques. We are confident our samples are large enough to represent the real world.

VI. RELATED WORK

Next to work discussed in Section II and Section V, work from the following domains is complementary:

Library Popularity Measures. Raemaekers et al. [10], [51], [30] performed several studies on the Maven repositories about the relation between usage popularity and system properties such as size, stability and encapsulation. Popularity has also been leveraged in IDEs [23].

Code Search and Recommendations. Code search is prominent among research on software reuse with many benefits for system maintainers [52]. Examples of available code search engines are google code [53]. Research tools such as Ichi-tracker [54], Spars [50], MUDAbblue [55] and ParserWeb [56] are just a few of many available search tools that crawl software repositories mining different software attributes and patterns with different intentions.

Software Systems as Components Within an Ecosystem. Recently, there has been an increase in research that perceives software systems as being components that interact and form dynamic relationships within an ecosystem. Work such as Bosch [46] have studied the transition from Product Lines to an Software Ecosystem level of abstraction. German et al. [31] studied the GNU R project as an ecosystem over time. Bogart et al. [12] studied how different ecosystems deal with API changes of their evolving libraries. The results show differences in each ecosystem policy and its supporting infrastructure; and there is value in making community values and accepted tradeoffs explicit and transparent in order to resolve conflicts and negotiate change-related costs. Furthermore, Mens et al. [57] performed ecological studies of open source software ecosystems with similar results. Other recent work has been related to dependency networks [18], [58].

VII. FUTURE WORK AND CONCLUSION

In this paper, we present the SUG model as a means to represent, query and visualize different super repositories in a standardized and systematic manner. Immediate future work focuses on evaluating the insights of these queries and visualizations with actual system maintainers. Combining its “wisdom-of-the-crowd” insights with complementary work on compatibility checking of API changes, should give rise to a comprehensive recommendation system for effective dependency management.
